1835-36

THE

FARMERS' REGISTER,

A MONTHLY PUBLICATION

Devoted to the improvement of the Practice,

AND

SUPPORT OF THE INTERESTS OF AGRICULTURE.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

And he gave it for his opinion, "that whoever could make two ears of corn, or two blades of grass to grow upon a spot of ground where only one grew before, would deserve better of mankind, and do more essential service to his country, than the whole race of politicians put together." *Swift.*

VOL. III.

PETERSBURG, VA.

PUBLISHED BY THE PROPRIETOR,

1836.

TABLE OF CONTENTS OF VOL. III.

A

Abolition Societies, movements of, and anticipated results 287
Address of James M. Garnett, President, to the Agricultural Society of Fredericksburg 615
Address of T. M. Bondurant, President of the Buckingham Agricultural Society 503
Address of James Barbour, President, to the Agricultural Convention 685
Advice asked for, and comments thereon 447
Agriculture, the unsettled state of opinions on 140
Agriculture of Virginia sketch of its progress, and causes of its decline and depression—an Address to the Historical and Philosophical Society, by Edmund Ruffin 748
Agriculture of Virginia and the Northern States, comparative view of 186
Agriculture of the United States, Strickland's observations on 201
Agricultural Society of Buckingham, proceedings of 502
Agricultural Society of Fredericksburg, proceedings of 565
Agricultural Society of Albemarle, proceedings of 566
Agricultural Society of Florida, proceedings of 567
Agricultural Society of Rockbridge, notice of by R. R. Barton 607
Agricultural books and papers published in the United States 134
Agricultural Convention, remarks on its plan and objects 556, 619; hints for its consideration 556; proceedings of 620; petition of, to the Legislature of Virginia 620
Agricultural professorship, advantages of one being instituted in Va., by Gov. James Barbour 274
Agricultural Societies, remarks on their constitutions, and usual procedure 575
Agricultural publications, influence of 141
Agricultural publications, low priced, remarks on 226
Amherst tillage, &c. of, by an Amherst Farmer 104
Analogy, vegetable and animal, 229
Animalized charcoal, offal of sugar refineries, a new and valuable manure 568
Anonymous writers, a proposition to exclude 507
Ants, to destroy 291
Apple tree, of large size 479
Apple trees, soils suitable to 168
Architecture, submarine, of the Alexandria aqueduct, 90
Artesian wells—depths of the most remarkable, and uses of 82
Ashes, as manure 137, 175; of anthracite coal 232

B

Back river lands, described by "A Gleaner"
Bacon, to cure well—the Smithfield method 554
Barbour, James, on the advantages of an agricultural professorship, 274; his Address to the Agricultural Convention, 685
Barton, R. R., on the Rockbridge Agricultural Society—silk business—and internal improvements in Virginia., 607
Bee-moth, to get rid of, 367
Bees, management of, 370; burying, to pass through the winter 109
Beet-root, cultivation of in France 290
Benners, L., his improvements by marling 225
Bleaching mania 423
Bone manure for corn, by A. Nicol 474
Bones, as manure, general account of, by Sir John Sinclair 596
Bones of whales, proposed to be brought into England for manure 292
Booth, E. G., on making Irish Potatoes and mangel wurtzel 434
Bread fruit tree, seeds sent by J. S. Skinner 316
Breeding stock, important facts observed in regard to 51
Breeding, principles of 87
Briers, to destroy 282
British Farmers' Magazine borrows without giving due credit, 511; further remarks on 716
Broom corn, its culture, cost, and profit 176
Buffaloe, Petrified, 213
Buffaloe Berry, account of 35
Buhr stone in Va., by W. S. Morton 677
Buildings destroyed by gunpowder, to arrest fires 595
Burwell, Nathaniel, on wheat and cheat growing from the same root, 556

C

Cabbages, to keep in winter 492
Calcareous earth, remarks on, and objections to that term being limited to carbonate of lime—by J. E. Muse, 664, 665. Remarks in reply 665
Calcareous earth, for manure, discovered in Western Pennsylvania 169
Calcareous rocks, in Mecklenburg, Prince Edward and Chesterfield, by W. S. Morton 517—remarks on 516
Camak, James, on corn made without tillage 454
Camel-lighters for carrying marl, described by H. 501
Campbell, C. furnishes notes from old authors, on Va., 483
Campbell, Hugh, on tarring seed corn 725
Canada plums 260
Canal, Chesapeake and Ohio, state of 135, 447
Canal boats, swift, 21, unparalleled speed of 194
Canal, &c., of the James River and Kanawha, its expected beneficial effects in checking emigration, by T. R. Dew 133
Canal, Erie, enlargement of 275
Carbon, animalized, a new manure, account of 120; account of its falsification 120
Carmichael, Wm. his experiments on the effect of depriving corn of the green fodder 661; describes his machine for raising marl 290
Cats, anecdotes of 474
Cattle, short-horned breed, origin and value of 159; list of animals, and prices at which they sold 162
Cauliflower, culture of 424
Celery, to preserve through winter 281
Cement, American, a new and valuable invention 148
Champagne, American, manufacture of 213
Chondrometer, for ascertaining the weight of grain—by James M. Garnett 286
"Charity thinketh no evil" by "Marler" 542

Cheat, convertibility of wheat to 431, 555; proofs of being derived from wheat, by Thomas Carter, 276
Cheese, Parmesan 163
Cheese, making and preservation of 10
Chemistry, on the utility of, to agriculture and horticulture 717
Chincoteague Island, and its wild horses, 417
Christian, James H., gives details of manuring, &c., 149
Cinders, blacksmith's, value of as manure, by W. S. Morton 546
Climate, Kenrick's remarks on 430
Clover hay, curing of 107
Clover seed, directions for saving 282, method in France, 285
Clover and plaster used successfully for improving worn-out land, by Catlett Conway 444
Clover, on the mode of its benefiting a succeeding crop of wheat 296
Coal gas, refuse of, important use of 196
Cocoons, successive crops of 473
Coffee, Florida, by H. B. C. 232
Coffee, substitute for 214
Cold, the bad effects on our soils and their products; by J. R., 252
Comments on various papers of the Farmers' Register, No. 10, vol. II, by Commentator 111—on papers of No. 11, 114
Commercial reports, monthly, 64, 189, 318, 383, 510, 511, 639, 704, 767
Common grazing, the legal right of, by Jeremiah, 592
Communications on small matters, generally the most useful 44
Conway, Catlett, corrects a mistake in the publication, 546—on improving worn land by clover and plaster 444
Cooking with gas, as fuel 9
Corn, Indian, how made without tillage, by James Camak, 454; comparative value of different kinds 16; Tunicata, by N. Herbemont, 447; seed of, selection of, 722; on tarring, by Hugh Campbell, 723; experiments on gathering it early, and drying it in ventilated pens, by E. R. 634; advantage of cultivating by cross ploughing, by A. S. F. 495; on the tillage of, by J. P. 614; statement of a crop of, on Staunton river land, by G. W. Read, 478; experiments to shew the injury it receives from the fodder being taken off, by Wm. Carmichael 661; large crop of in Goochland 574; on kilns for drying by W. O. Gregory 251; experiments in topping 369; seed, on tarring 14; to lessen the cost of replanting, by E. R. 445; green, dried for table use in winter 25; large yield of, by A. S. Foreman 470
Corn, twin, notice of, by P. J. Derieux 434
Corn crop, mode of securing and value of its offal, by Agricola 346
Cornstalks, on saving and preparing them as food for cattle, by Agricola 91
Correspondence, private, extracts from 191
Cotton gin, Whittemore's improved, advantages of 179
Cotton seed, an article of food, by H. B. C. 232
Cotton, cultivation of on prairie lands, by "A Planter," 409
Cotton, machine to gather from the balls in the field 678
Cotton, on the different kinds of, by James Davis, 469
Cotton, on the fraudulent packing of 700
Cows, on spaying, 726; detailed cases of 747
Cows, spayed, improved thereby for giving milk 166, 183—the process directed 167
Cows, on milking, by Gideon B. Smith 231
Couch (or wire) grass, its value as forage 715
Croom, H. B. encloses a communication on marling 225
Crops, mixed, on the cultivation of, by Agricola 344
Crops, large and successive, of corn, rye and hay, 513
Crops in Bedford, state of, by Micajah Davis, jr., 227
Crops, principles of the succession or rotation of, by Chaptal 527
Crops, rotation of. 222, 412
Crops mixed, their culture, by Agricola 90
Cut-worm, its ravages lessened by planting corn in ashes and lime—destroyed by poultry 353—method for the destruction of, by T. B. Watkins, 296

D

Dairy, general economy and management of 10, produce of 77
Darnel or spelt, European opinions of 716
Date trees in Georgia 246
Davis, James, on the different kinds of cotton 469
Davis, M., on state of crops, and agricultural publications 227
Debtors, list of, 469
Derieux, P. J. on twin corn 434; on old practices and new doctrines, 540
Dew, Professor, on the central canal, &c. of Virginia, 133. On Price 65, additional note to, 128
Dickinson, John, on the improvement of Va.—silk culture, marling, and female labor, 475
Digging machine, worked by steam 281
Discontinuances of subscriptions, a chapter on, 256
Diseases of wheat, on Mr. Bauer's discoveries, by A. Nicol 59
Dog, a remarkable and destructive one 312
Dogs, wild, of Van Diemen's Land 254
Draining and reclaiming low lands, and straightening streams, by N. E. Read, 299
Dry rot, Kyan's patent to prevent, by the use of corrosive sublimate 592
Ducatel, Professor J. T., review of his geological report of Maryland 36

E

Earth and its inhabitants, speculations on the ancient state of 411
Earth, sinking of portion in Prince William county 149
Editorial remarks—on communications on small matters 44—on the evils to Va., of the present law of enclosures 49—on frauds committed in sales in England of American lands 57—season, state of crops, and prospects, in May, 1835, 63—on the phenomenon of the "black waters" 64—on the Essay on Price 65—on the milk weed 166—four shift rotations 114—provincial terms 118, animalized carbon 120—on experiments on the effect of heat on gypsum 126—delinquent subscribers 128—on the relation of certain plants to the ingredients of the soils on which they grow 129 and 441—the importance of calcareous soils for vineyards 130—on potash and ashes as manures 138—on Professor Rafinesque's invention of steam ploughs—incombustible houses, &c., 141—on the economical effect of labor-saving inventions 144—quick lime on newly cleared land 157—on the use of scientific and provincial terms in agricultural papers 153—fertility of the old sites of dwelling houses 159—on the spaying of milch cows 166—on party spirit 174—postmasters, legal responsibility of, to publishers 175—on the peculiar claims of the Farmer's Register to southern support 181—plan of a labyrinth 185—season and state of crops,

June 1838, 190—on mistakes as to payments 191, to correspondents and readers—subscribers and contributors 192—on Mr. Bonners' marling 226—on low priced agricultural publications 226—on patronage to 227—on the unfitness of seeds of Chinese mulberry for propagating the kind 252—blue stem and turkey wheat 255—on seasons and crops, state of in July 255—on discontinuances of subscriptions 256—on the marl underlying Norfolk, Va. 263—on the communication of "Subscriber" 272—on the proposal of an agricultural professorship, and of an agricultural convention 275—on cheat and wheat growing from the same root 276—on the inefficacy of putrescent manure alone on soils naturally poor 276—on the movements of the abolition societies, and the anticipated results 287—season and crops in August 319—terms of publication and notices to subscribers 320, 384—on the mode of saving fodder by cutting down the stalks 347—on Stevens' Treatise on Irrigation 347—on the communications of "A Planter" on prairie soils 355—on the Essay on Lime, by M. Puvis 359, and in notes to 366—and also from 385 to 391—on the fallacy of the usual modes of choosing seed for the best kinds of wheat and other grain 323—on green sand, Jersey marl, or gypseous earth 422—on the habits of emancipated slaves 429—on the use of the native mulberry leaves for silk worms 433—old writers on Va. 439—on applications for advice and instruction 447—on Tunicata corn 448—on the superior value of the communication of *facts* 448—season and state of crops in October 448—on the effects of the law of descents, and law of enclosures, on agricultural interests 458—on scorzonera as food for silk worms 472—on flooding and irrigation in warm regions 484—on the puffing system 508—on the course of the British Farmers' Magazine in regard to the Farmers' Register, and Essay on Calcareous Manures 512 and 716—season and state of crops in November 512—on composition of calcareous rocks of Prince Edward, Mecklenburg and Chesterfield 516—on Mr. Walker's communications 536—on the habits of the Shakers, and the value of their institution and labors to national interests 544,—on Mr. Fontaine's experiments on fodder, and observations on marl 553—on the steps taken and the promise of the agricultural convention 556—on the calcareous ingredients of soils from Arkansas 557—on animalized charcoal as manure 568—on constitutions of agricultural societies 575—on facilitating the analyzing of marl 575—on horse feeding and management, and usual errors therein 591—on blowing up houses to arrest the progress of fire 594—on the new discovery of compressing air for mechanical power 595—on the error of Sinclair's opinions on oyster shells as manure 600—on Malthus' theory of population 602—on the transactions of the Geological Society of Pennsylvania 613—on the discussion as to the size of farms, and the policy of Va. in altering sizes and boundaries 641—on the great loss of value in using fish manure without combining it with calcareous earth 654—on the superiority of Va. to the Northern States, for silk culture 674—on the labors of the Marquis de Turbilly 678—introduction to M. Puvis' essay on marl as manure 690, marginal notes and comments thereon 691, 692, 693, 694, 705, 706, 708, 709, 700—on the fraudulent packing of cotton 709—on feeding silkworms on the leaves of the Osage orange 701—on liming in Delaware, remarks on 703, on season and state of crops in February 704—on darnel or spelt 715—on premiums for increase of population 724—on the question of propagating the Chinese mulberry by seeds 734—on the propagation of the Chinese mulberry 736—on closing the 3d volume 763—on the geological survey of New York 768

Eggs, preserved by lime-water 614

Electro-magnetism applied to mechanical operations 367

Enclosures, on the ill policy of reducing their number, by Fencemore 455

Emigration from Va., its baneful effects 138

Ewe, remarkable fecundity of, by E. R. 271

F

Farms, large, the superior advantages of, advocated, 641—small, the superior advantages of, advocated, 643

Farms, large and small, the case stated as to their relative advantages and disadvantages 641

Farms, select, in France, report of a committee of examination on 131

Farmers' proverbs 134

Farming, small, large products from, by J. L. 410

Farming and general economy of the Shakers 544

Featherstonhaugh, G. W. extract from a review of his geological report 733

Female labor, low price for 375

Female laborers, observations on the low price of the wages of, by Polecon, No. 1, 257, No. 2, 379—and No. 3, 435

Fence law, objected to by Fenceless 259

Fence law, its operation on the poor, by Waqua 31—its general policy defended, by Fencemore 47

Fig, account of the kinds, and culture of, 237

Fish, a strange kind caught near Norfolk, Va. 275

Fish, gold, raised in warm water in England 683

Fishes, vast number of, 296

Flies, house, to exclude, 289

Flooding lands, the advantages of, in warm climates, 484

Florida, on the soils, products and agricultural advantages of, by F. Macrae 179, 228, 372 and 515

Fodder, experiments of the effects of gathering and treating in different modes, on the corn, by W. S. Fontaine 549

Fontaine, W. S. report of his experiments on fodder and corn, 549, on calcareous manures, and some facts observed in connexion 551

Forest trees of America, catalogue and descriptions, from Michaux 94

Frederick and Jefferson counties—remarks on the character of the country and system of calculation by a Frederick Farmer 23

Frogs, introduction of into Ireland, 33

Fruit, high priced, 368

Fruit drier 308

Fruits, on the decline of old varieties and production of new 524

Fruit trees, diseases and enemies of 312; on scraping, 292; on transplanting 590

G

Galen's reply to Commentator 230

Garlic, wild, means to destroy 393

Garnett, James M. his address to the Agricultural Society of Fredericksburg 615

Garnett, James M. on the pocket chondrometer, and skinless oats 286—on drilled wheat—queries 340

Gas, cooking with as fuel, 9, 293

Geology, Professor Silliman's lecture on 310

Geology, importance of its principles to mining operations 196

Geological Society of Pennsylvania, remarks on the transactions of 613

Germination, quickening of, 214

Gibbon, J. H. on the uses and culture of Ruta Baga 240

Gold mines of the United States—on the probable diminished product, and early exhaustion of 738

Gold mining Company, the Union, of Va. 143

Grafted trees, Mr. Knight's opinion of deemed erroneous 163

Grafted fruits, influence of the stocks on 510

Grape, the To Kalon 678

Grass, ribbon, account of 223, 479, 727
Grass, orchard, on the culture of, by A. Nicol 72
Grass, Herds, on salt marsh, by J. B. Marsh 126
Grasses, artificial, on the management of, 249
Green sand, (or Jersey marl,) speculations on its nature, and fertilizing properties, by Willoughby Newton 419—remarks on 422
Green sand, region of in Va. described by Professor Wm. B. Rogers, in the report of his geological reconnoissance 636
Gregory, W. O. on corn kilns, and cheat controversy 251
Gypsum, effects of on Tobacco, tested by a series of experiments, by Anderson C. Morton 547
Gypsum, on preparing for use by heat 519; not injured by being heated, by J. D. 266, and by A. Nicol 125

H

Hailstorm, destructive, in Va. 116
Hammering stone by steam 144, 119
Harper, P. W. on the tobacco crop 719
Harrison, Wm. B. his rejoinder to the defence of the four-field rotation 245
Harrow, on covering corn with, by E. R. 444
Hay, late mowed 293
Heat, injurious effects of, on cultivated land, by J. R. Wallace 33
Hemp and silk culture, the profits of compared 612
Herbemont, N. on Tunicata corn 447; corrects mistake respecting "vin muet" 227; on the Chickasaw pea, and pea fodder 93
Hessian fly, supposed mistake as to, by H. H. R. 261; its injuries not avoided by liming seed wheat, by "Crooked Run" 43, and by E. R. 651; effect of sowing quicklime on the maggots, by Wm. M. Tate 252
Hogs, on the causes of their diseases, by Agricola 353, on raising and fattening, by Agricola 357; new disease of, 127; swelling in the throat of, to cure, 633; on fattening, by "Incognito" 722
Holmes T. describes the sea islands, and the breed of wild horses thereon 417
Hooks in horses 733
Hops, culture and value of 245
Horse, the vices and disagreeable or dangerous habits of, described separately and at length 99, 179
Horse power compared with steam power 394
Horses and mules, working, facts as to their feeding, by W. 599, remarks on their usual bad treatment 590
Horses, race or high-blooded, the losses sustained by their being reared for sale in Va. by Gulley 652
Horses, manner of feeding in Flanders 9
Horses, their supposed disease of hooks 733
Horses, working, on the abuse and proper treatment of, by R. C. 726
Horses, the wild breed of, on Chincoteague island, by T. Holmes, 417
Horse-shoe machine, Burden's 144
Horticulture, party spirit in, 173
Hyacinths in glasses and pots, 493

I

Ice business, carried on in the north, for exportation 110
Improvement of Va. remarks on by John Dickinson 475
India rubber (or gum elastic) vegetable production of, and its application to manufactures 174; solvent of, 294
Insects, trade in, in Brazil, 148
Insects, their structures of calcareous rock 430
Iron ore, remarkable deposite of, 116
Irrigation in Italy 163
Irrigation, in Massachusetts, statement of 195; its advantages in Massachusetts 766
Irrigation of gardens 247
Irrigation, Treatise on 347, 449
Irrigation by catch-work 396

J

James River and Kanawha Company, proceedings of, 85, and 184
Jefferson's opinions on tobacco culture commented on 513

L

Labyrinth, plan of 185
Lactoline—desiccated milk, 127
Lake, subterranean, and its inhabitants 35
Land, improvement of, observations and inquiries on, by "Charlotte County" 284
Lands in Virginia, sale of in London 57
Lands, on the prices and products of 372
Law of enclosures, objected to 259
Lead ore and mines in Missouri, account of 144
Lice on cattle, how to kill 72, and by H. H. C. 261
Lice on fowls, destroyed by dry ashes 150
Lime, as manure, Essay on, by M. Puvis 359, 385
Lime as manure, experiments with, by A. S. F. 262
Lime, fertilizing properties of 111
Lime, importance of to the lower Eastern Shore counties 470
Liming in Lehigh 231
Liming in Delaware 703
Llama of Peru 234
Locust and mulberry trees for timber 72
Locust, mountain (robinia pseudaracia) mistakes respecting its growth and localities corrected, by J. G. C. 313
Lucern, 251

M

Machine for felling trees 424
Machine to gather cotton 678
Machine for mowing 224
Machine for raising marl, by Wm. Carmichael, 290
McDuffie, Gov. on protecting duties—slavery, and the attempts for its abolition 571
Macrae, F. on the forms of overseer's journals and monthly reports, 163—describes the soil, agriculture, &c. of Florida 179, 228, 527, 515
Mangel wurtzel, or field beet, management, uses and value of. 52
Mangel wurtzel, by E. G. Booth 434
Manure, sea weed 410, potash, 137, ashes 137, 175
Manure, on the necessity of making, by Simon Pure, 736
Manure from fish—profitable effects of, 653—ignorance and neglect of its greatest value 654
Manure, on making 523
Manure, what crops it should be applied to, 16
Manure, liquid, 313
Manure—land, 367
Manure, on poor soils, by T. B. A. 376 and by M. D.
Manures, putrescent, general treatise on, 559, 533, 654, 729
Manures, putrescent, extracts from Low's Elements of Agriculture 77, compost 729
Manures, putrescent, observations on, by J. M. G. 55
Manures, general report on, by N. Herbemont, 603
Manuring, practical details of, by James H. Christian, 149; queries and desultory remarks on, by T. W. P., 157
Manuring, surface, J. M. G. 60
Manuring by ploughing under green crops 291
Marble, valuable kinds near Lynchburg, 55

Mares and foals, management of, 87
Marl as manure, Essay on by M. Puvis, translated from the French, 690, 705
Marl, on means for facilitating the analyzing of 575
Marl, great depth of, underlying Norfolk, Va., and its quality 269
Marl of Tennessee, described by Professor Troost, 696
Marl region of Va., described in the report of the geological reconnoissance, by Professor Wm. B. Rogers 627
Marling, statement of its effects on a poor farm, by T. M. Stubblefield, 554
Marling, improvements by in North Carolina, by L. Benners, 225
Marling labors of John Moore, by E. R. 310
Marling, effects of, by Subscriber, 272
Matoaca Manufacturing Company 248
Meadow, on making 312
Milk, how preserved for long voyages, 369
Milk weed, (Asclepias Syriaca,) account of, 105—remarks on, 106
Mine, inundation of 703
Mistakes in payments, and the means of amending or correcting them 191
Mite, cheese, natural history of, 580
Moon, influence of on vegetation 142
Moore, John, account of his marling labors, executed under great disadvantages
Morton, Anderson C. on experiments with gypsum on tobacco, 547
Morton, W. S. on calcareous rocks and gypsum found in the middle region of Va. 517—on the use of blacksmith's cinders as manure 546—on buhr stone in Va.—iron ore—clay for bricks—and charcoal as manure 677
Mulberry, seed time of, 283; on the profits and increase of, 465—poor and dry soils best for, 465; on its culture 416
Mulberry, native, improper opinions of its unfitness for silkworms 433
Mulberry, Chinese, opinions and facts for, and against its being propagated by seeds 253, 734, 735, 736; on its properties and mode of propagation 689, 466, 481
Mulberry, White Italian, directions for sowing and raising 309
Mulberry trees, profit from a few 163
Mulberry leaves, a profitable crop of 253
Mule's colt, another from the same dam, 384, 440
Muse, Joseph E. on calcareous manures, and the improper limitation of the term "calcareous earth" 664, 665
Mushrooms, cultivation of, 211; new mode of growing 725; raising from the mushroom stone 728

N

Nature furnishes rules to direct agricultural operations 52
Nelson, Thomas C. on the conversion of wheat to cheat 555
New England, on the climate and soil of 291
Newton, Willoughby, on the nature and fertilizing properties of green sand, or "Jersey marl" 419
Nicol, A. on effects of heat on gypsum 125, remarks on his experiments 126; on Mr. Bauer's discoveries respecting the diseases of wheat, 59
Northampton, (Eastern shore of Va.) notes of a hasty view of the soil and agriculture of 233

O

Oat, skinless, unproductiveness of, by Wm. Prince & Sons 564; statement of the product of, by James M. Garnett, 287
Oil, of cotton seed, 50
Oils, vegetable, on the preparation of, 294
Olive trees in Georgia, 246
Orange trees in Georgia, 246
Osage orange, (Maclura Aurantiaca,) account of 35; by T. S. P. 513; its leaves a good substitute for those of the mulberry 702
Ovens for hatching eggs in Egypt, 78

THE FARMERS' REGISTER.

Vol. III. MAY, 1835. No. 1.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

DEFENCE OF THE FOUR-SHIFT ROTATION, IN ANSWER TO W. B. H.

To the Editor of the Farmers' Register.

Westover, March 10th, 1835.

It has been my intention for some time past, to answer the objections to the four-field and fallow system, set forth in a communication under the signature of W. B. H., in your January No.; but have been prevented from doing so, at an earlier period, from obstacles not altogether within my control. I am prompted to such a course, not for the mere sake of writing, (for there is nothing that I abominate more) but in vindication of practical opinions, advanced by myself in a former essay—viz. the recommendation and justification of the four-field and fallow system. I will not feign ignorance of the author of the communication alluded to; no, I feel a pride in acknowledging that it has sprung from so high a source: for it could not have originated from one that I more highly respect and esteem, and whose opinions would command more consideration—and an admonition of my *imprudence*, in recommending any particular system, comes with mighty force from that respected writer. But he must pardon me for entertaining such confidence in my agricultural opinions, as have resulted from experience; and which have been countenanced and approved by better heads than mine. The objections and arguments of my friend seem plausible enough, and if not properly considered, tested, and refuted, must consign to oblivion all that I have before said in vindication of the system I have recommended to the public. My object in the present essay, therefore, is to refute, as far as it is in my power, the objections which have been urged, and to place the system, if I can, upon stronger grounds, by yet stronger testimony in its favor.

But before entering upon the main subject of this essay, let me express my entire concurrence with W. B. H. in the opinions he has expressed, with regard to the four-field system of *Arator*. Yes, and let me go a step farther, and say, that if the theory and practice of that great agriculturist and public benefactor had been persisted in, and not received the frowns of prejudiced men, Virginia would long ago have been aroused and resuscitated from her impoverished condition, and would now be ready to adopt the more rigid and profitable system of three successive grain crops in four years. There is a tendency in human nature to mar and throw a shade over the enterprising and laudable intentions of some. Perhaps this is a frailty inherent in us. But at the same time that I agree with him in justifying the system of Arator, I must express my astonishment at his concurrence with that highly intelligent gentleman, Mr. John Wickham, in condemning the adoption, more generally, of the four-field and fallow system. Yes, a system which I understand one or both have adopted, and are now practising. It does not appear either generous or consistent, for a farmer to denounce to others, a system which he pursues with perseverance and profit. Can it be that my learned friend designedly acts against his own precepts? *Video meliora probaque, deteriora sequor.* It may be said that this system has been tried, and that it will not do. Let me tell W. B. H. that he has plucked it in its bud, before it has unfurled itself for him to reap its full benefit. It is condemned before it has had a fair trial, or one round of crops. I would ask, has it not paid him well? Has it not cleared his land of all pests, and improved its fertility? And is not his farm in a better state to afford him both pleasure and profit than before he commenced it? I must be vastly mistaken if it is not; and can assure him, that it will carry with it both profit and improvement as its rotation rolls around.

As I am furnished with no written data, by those who pursue the three-field course, (which seems to me to be rather unkind,) I shall be governed in the comparisons I may make, by my own observations, and what information I have been able to collect from many highly respectable and intelligent gentlemen who have pursued it; and therefore shall be regulated by their practices and results, both on large and small estates.

The first objection of W. B. H. which he deems "insuperable, is its expensiveness, which expense, consists in keeping a supernumerary number of horses, which are only employed at one season of the year, (and that the fallowing season) and kept at a heavy expense the rest." I will ask the gentleman what number of horses would be necessary for the judicious cultivation of a farm of 400 acres under the three-field course? I use twelve mules. With this team I fallowed with ease this fall 100 acres, in five weeks; and during the greater portion of this time the season was excessively dry. Now, *vice versa*, let me ask what this team would have been employed about if they had not been fallowing? Why, I should say idle; and consequently supported at a "heavy expense." For, after the wheat is thrashed, and the corn laid by, which is always accomplished by the middle of August, the teams would have nothing to do until seeding time, were they not employed in this. I should therefore think the labor much more equally distributed under the four than the three-field course. I have never yet seen the day that my teams had not as much as they could do; and sincerely think the fallow season for wheat is the most leisure one we have. The ploughs are kept running at their leisure, having nothing to interrupt them, while the manual labor is employed in gathering and securing the fodder, &c. The fallow field is always ready, and frequently (by the time the corn would admit of being removed,) we have ploughed much of our corn land before the season had arrived for seeding. Many persons have been deterred from fallowing, in consequence of the droughts. I have never yet been compelled to stop a day from that cause, and know I have as stiff land to encounter as any one. It may be attributed in a great measure, to the peculiar advantages of our system, viz: the non-grazing, and the constant stirring of our soil. The land is so frequently turned over, and that deeply, that it never becomes so very hard and tenacious as to cause a suspension in our operations. It is also mellowed and kept porous by the shade and roots of the clover, and the great quantity of other vegetable matter which is given to it. It is worthy of consideration, too, that three-fourths of the entire farm receives the ameliorating effects of the frost. It is true, that I have found it advisable for the relief of the teams to double them, or add one or two more to a plough; and have ploughed with as many as five; but this has rarely occurred—only once in eleven years. It is a great fault with Virginia farmers generally, that they keep too little team. Their work is frequently badly executed, and it results from this false economy. If I were to pursue the three-field rotation, (and which I certainly never shall) I should unquestionably keep and consider this number of horses (or rather mules) necessary. It will be recollected that I work but few oxen—so few as scarcely to be taken into consideration. Having more corn land to put in wheat, and more in corn, I should consider it not more than sufficient at those particular seasons; for it is the corn land with me that is so difficult to seed. The land is most always grassy, and of a wet season it is frequently almost impossible to plough on account of this impediment. This fall I seeded 100 acres of fallow in seven days, and was nearly four weeks seeding 68 acres of corn land. After the fallow is finished, by the last of September, it rarely requires more than harrowing in. The corn land has to have the corn removed, and to be ploughed, harrowed, sowed, and then harrowed again, at the most pressing season; for at this crisis, there must be no time lost, or the season has passed. Your corn land for wheat should be better drained, being more liable to suffer from water, not having the vegetable matter in it which the clover fallow has. It has to lie out longer, and if not drained with care, your clover may be killed from wet in a hard winter. You know, that in a farm of 400 acres, there is only 33⅓ acres of land in cultivation under the three-field course more than you would cultivate under the four-field course, and this is in the fallow for wheat, and which I have before said is done when the teams would have nothing else to do were they not so employed. There will be too, an additional 33⅓ acres in corn under the three-field course, and about which you are engaged in some way, the whole year. Now, I believe it is universally admitted, that all land intended for corn (perhaps it would be better to say all stiff soils) should be turned up as early in the winter as possible, for reasons which it would be superfluous here to mention. How rarely do we see it done. And why? Because we have not had time, having so much of it to do. I should say, as our winters are so variable and uncertain, that this would be a season of unusual pressure: more, or as much so as the seeding season—for when the weather opens, every exertion has to be made to get through in due time. We are enabled the better to get through it in the proper time, because we have less of it to do. I should remark, that as the wheat crop will be much less, and consequently under the three-field course will take a shorter time to thrash and deliver, the teams would be kept at this heavy expense the longer. The time for seeding wheat being short and limited, that system should be pursued by which we can get in the most in this given time, and at the least expense. I would ask why it is that those who pursue the three-field rotation do not finish seeding before those who fallow? Not in consequence of the excess of team; assuredly not: but because we have had six or eight weeks to prepare one-half of our whole surface, while on the other hand you are doing nothing towards it. It is put in, in a few days, before you are scarcely ready to commence, or at least the fallow land can be sowed, while you are seeding the excess of corn land. There is only one-ninth more land in cultivation annually under the four than the three-field course, and this ninth is the fallow, which as I have repeated before, is done when we should be unemployed with our teams, and we should have two-ninths more in wheat. Now let me inquire, which would be the greater press of the two, to prepare and seed two-ninths in ten or twelve weeks, or to prepare and seed one-ninth in four weeks. Again, by way of farther illustration, suppose we had but one team, say two or three horses; which would be the most easily accomplished, to prepare and seed with the same team and hands two-ninths in ten or twelve weeks, (which time you would have, say until the last of October,) or to seed one-ninth in four weeks, having the corn to remove? You could not commence ploughing for the latter, before the former would be already prepared, and would require but harrowing in, which may be done in a few days. In the other case, if the month of October should be a very wet one, you would have but little or no wheat seeded. One may be accomplished, and the other might be impossible. This may be thought an extreme case, but it matters not, as it goes to show the principle, and in the same ratio with the entire crop, will the fallow be sown. Finally, if I were to choose between putting 133⅓ acres of land in wheat and cultivating 133⅓ in corn, and putting 200 acres in wheat, one-half fallow, and cultivating 100 acres in corn, with the same team and hands, I should unhesitatingly choose the latter, independent of its greater reward, as I shall presently show.

As W. B. H. is such an advocate for a substitution of horse-power for manual labor in some other respects, I am surprised he should be so unfriendly to the fallow system, which is accomplished almost entirely by their agency. A farm can be improved and profitably managed, with a good team and few hands, but it cannot be with a good force of hands, and an indifferent team. The expense of the one will be small compared with the other, taking into consideration the first cost, &c. I shall ever bear in mind the opinion once expressed to me upon this subject, of a good practical and strictly economical farmer, who had accumulated quite a large fortune by tilling a poor soil, the late Major James Dillard of Sussex county. He wondered that farmers generally, and particularly on the wheat estates on James River, did not keep more team than they did. He was once of the impression, that more than enough merely to till the soil, and that very imperfectly, were eating up their owners; but by experience had found out his error, and then thought a double team economy. He had substituted mules for oxen almost entirely. He believed oxen kept to perform much hard work, would cost as much as mules—being obliged to be fed with grain, &c., and then not capable of performing one-third the labor. His mode of supporting this extra team, was in the following way. During the winter they were penned in the usual way that we do our stock, except having a more complete shelter to protect them from the weather. These pens were kept well littered with corn stalks, &c. which he considered as good food as they required—and he gave them rarely any grain. After the grass put out they were of no more trouble or expense, except when used. At particular seasons when the services of the whole were required, you could have your work done speedily and effectually. I concur in the opinion of this worthy gentleman, and do believe if we were to keep a double team of mules, and abandon almost the use of oxen, (for from the peculiarities of our situation and climate, particularly in the tide-water section of Virginia, they are comparatively of but little value) we should find it greatly to our advantage. What few I have, eat more grain during winter, than my mules, and cannot do one-third the work—mules are hardier and more long lived animals, and fed in this way, would make more manure, and that better.

The next objection which W. B. H. says is of a formidable character, is that "the more valuable crop, corn, is sacrificed in part, to the crop of wheat, which is less safe."

As I have before said, gentlemen who have raised objections to this system, have furnished no written data by which to be governed. I shall therefore allow in my comparisons the most liberal crops that I have ever heard of, any year, under the three-field rotation, and compare them with my own under the four-field; and in this comparison shall be governed, also, in what I believe my own estate would make under the same system, and under the most favorable circumstances. In getting an average price of the crops of both wheat and corn for the last five years, I have been furnished with such as I may quote, by reference to the journal of a friend, who has regularly sold both crops. It will be unnecessary to state the prices each year, but take an average for the last five years—

The average price of wheat for that time has been, per bushel,	\$1 09½ cts.
The average price of corn for that time has been, per barrel,	2 93½

He says in a note, "the above prices are what I have sold at each year; but I ought to remark, that the prices of wheat are rather under the highest prices that wheat has sold for some years, as I did not always get the highest price for wheat; but the prices of corn are a little over the prices generally got in each year; as I have generally got a little over the market price for corn, as my corn is white and very nicely cleaned, and has a very high character in Petersburg."

When upon a former occasion it was stated by me, that one-fourth of a farm under the four-field and fallow system would produce more corn than one-third under the three-field, it was supposing the farm cultivated under the old plan, which I believe is still kept up, of grazing the one-third bare. For if a farm under that course has ever received the generous assistance of a standing pasture, I have certainly never seen or heard of it. Persons who pursue this course, are too tenacious of their soil for tillage, to appropriate it to so wasteful a purpose, as they think. And I am led to such a conclusion, also, from the knowledge and belief, that under the four-field course, the crops would increase from the increase of fertility; and under the other, would diminish for the want of this improvement—and still think one-fourth of a farm, in a series of years, under the four-field system, will produce more corn, than under the old three-field course. I may revert to this again.

I will now undertake to show to the satisfaction, I hope, of all impartial persons, that the corn crop is not so valuable a one as that of wheat. To effect this object, I shall give my average crops for the last five years, (or rather will give four crops) and will omit the crop of wheat of 1833, as I do not believe any one in this section of Virginia would admit that as any thing like an average crop, it having been destroyed by incessant falls of rain for nearly six weeks, and that when the wheat was nearly matured, an event never known with us before. My crop of that year, however, shall be taken into the calculation in its proper place, and allow the difference it would make in comparing the relative value of the two crops for the whole term of five years. I will first take the crops of wheat for the years 1830, 1, 2, and 4, and the crops of corn for four years also. I will remark, that my crop of corn of 1833 was 616 barrels. I was advised to stack the corn on the land while sowing wheat, that I might get through the quicker in seeding; it was the first time I had ever done so, and do believe I lost 100 barrels by the birds and wet weather; the land was scarcely ever in a condition to drive over without destroying much wheat, and on our narrow eleven feet beds, the carts, &c., filled up our water furrows so much, that I was until the spring before I succeeded in housing it. Corn should always be removed from the land intended for wheat, if possible. Our winters are so wet, that there will be much loss from depredations: and it is a crop which easily decays from exposure to the weather too long.

My average crops of wheat for the above mentioned four years have been 3114 bushels, which at the average price as above quoted is,	\$3409 83
My average crops of corn for four years, viz. 1830, 1, 2, and 3, are 435 barrels, which at the average price above quoted is, - - - -	1275 28
Gross amount under four-field course, if the entire crops had been sold,	\$4685 11
Now 133⅓ acres land in wheat under the three-field course, allowing an average of 12 bushels per acre, is 1600 bushels, which at the average price for wheat as above is, -	\$1752 00
133⅓ acres in corn, allowing an average of 5 barrels per acre, is 666 barrels, which at the average price as above is, - - - - - -	1954 71
	\$3706 71
Balance in favor of four-field system,	\$978 40

Cr.—difference in the "heavy item of expense" in seed wheat, - -	62 88
Dr.—difference in seed corn and clover seed, - - - - - -	15 52
	$900 00

Now here is a difference of $900 upon a small farm in favor of the four-field and fallow system, after allowing an average of 12 bushels of wheat per acre, and 5 barrels of corn, for the above years, which I trust will be considered a liberal one. Including my crop of wheat of 1833, which was 2300 bushels, (and which God grant I could take into the calculation as an average crop, for it promised to be at that advanced season, May and June, to be much the best I ever had,) it would make the balance in favor of the four-field $722. I have given the above average of 12 bushels of wheat, per acre, and 5 barrels of corn, as they are the best I have ever heard of any year, under the three-field course, and hope it will elicit from others, a more correct statement of their average for the years above quoted. Under my present impression, I do not think their crops have averaged 10 bushels of wheat, or 4 barrels of corn, where lime has not been used very extensively, if even then. Several good farms on James River *(possessed of the rich mellow soils, and the great natural fertility of mine,)* have not averaged 8 bushels of wheat, or $3\frac{1}{2}$ barrels of corn under the three-field course, as I have been told by their owners. Why is this so? Most assuredly in consequence of a defective system.

Again, let us continue our comparisons: my fallow for wheat has averaged $21\frac{1}{3}$ bushels per acre, and my corn land in wheat within a fraction of 10 bushels, viz. $\frac{931}{1000}$. You are told that corn will produce more money in a series of years, from the same land, than wheat—now let us see:

100 acres of fallow for 4 years has produced 2133 bushels, which at $1 09½ cts. is, - - - - -	$2335 63
100 acres in corn for 4 years, an average of 5 barrels, is 500 barrels at $2 93½ cts. is, - - - - -	1467 50
Amount in favor of fallow for wheat,	$868 13

An average of the two crops from fallow and corn land for wheat, is rather over 15½ bushels per acre, 100 acres at this is 1557 bushels, at average price is, - - - - -	$1704 91
The crop of corn from 100 acres would be, - - - - - -	1467 50
	$237 41

So that an average of the two crops of wheat from the fallow and corn land, will amount to more than the product of 100 acres from corn as a first crop. Again, let us see the difference between fallow first for wheat, and succeeded by corn; and corn the first crop, and succeeded by wheat.

Wheat from fallow field of 100 acres, an average of 2133 bushels at $1 09½ is, - - - - - -	$2335 63
Corn after wheat 435, on an average at $2 93½ is, - - - - -	1276 72
Amount from fallow for wheat, and corn after it, - - - - -	$3612 35
Corn as a first crop, 5 barrels per acre at $2 93½ is, - - - - -	1467 50
Wheat after corn at 12 bushels per acre is, - - - - - -	1314 00
	$2781 50
Balance in favor of fallow for wheat,	$830 85

But before concluding these comparisons, I will state a fact which will be somewhat more at home to W. B. H. The year I purchased this estate, (1829) my best field was put in corn after clover, by my worthy predecessor, (whose capacity to manage any crop, I am sure W. B. H. will acknowledge, and allow me to add my testimony in his behalf.) This field of 100 acres produced, under his directions, 7 or 8 barrels of corn to the acre, (I do not know the precise amount, but will say eight barrels:) now, from the price of corn that year, (1830) this 800 barrels would not have brought $1500. But we will allow the average as I have before done, and the amount that the 800 barrels would have brought, would be $2348. I put the very same land in wheat after clover in the fall of 1831, and the crop was 3000 bushels, which brought me £1000—more than double, if the crops had been sold as they were made; but we will carry out the average prices—

The product of this 100 acres from fallow, 3000 bushels at $1 09½ is,	$3285 00
The product of the same land in corn, 800 barrels at $2 93½ is, - -	2348 00
	$937 00

Here is a difference in favor of the wheat crop of $937, from the very same land, and both after clover. I hope that this statement alone will satisfy my friend that he is mistaken in supposing that the same land will produce more money from corn than from wheat, where an equal surface is devoted to each crop.

I am very sure that any of our James River lands (of course I do not mean our light sandy soils,) that will produce 4 barrels of corn to the acre, will also produce 20 bushels of wheat upon a good clover fallow, if well prepared and seeded. And do believe also, that land which will produce 8 barrels of corn to the acre, will produce from 25 to 30 bushels of wheat, after a good fallow. But to attain this, the earth must be well ploughed during the months of August and September, (nor should you stop your ploughs because the land is a little hard,) well harrowed, and then well sown and drained, and I will warrant the result. The fallow for wheat has paid me so much more than the corn land, that I am almost discouraged from seeding the latter. This fall, being stopped by heavy rains, I determined to seed a portion in oats, (one-fourth.) If it should result favorably, and the clover should succeed as well after it, I shall hereafter leave one-fourth to one-half for that crop, of my corn land, otherwise intended for wheat.

There are other considerations too, which should be borne in mind, in comparing the relative value of these two crops—one is, that the corn crop will not answer as a sale crop for persons living at a distance from navigation—as it will not afford transportation by land to any distance—which no doubt all calculating persons will take into consideration. Another very important consideration is, that the fallow system gives you so much more straw from which to make manure.

I do in my conscience believe, that a farm, say one of 400 acres, (as that is more familiar to me) will pay from $1000 to $1500 more under the four-field and fallow system, clear, than the same farm managed under the three-field course, in a series of years. The least I can say is, that the advantages in favor of the four-field, will be sufficient to defray all the necessary expenses attendant on the cultivation and management of such a farm.

W. B. H. next supposes the corn crop not sufficient to employ the hands advantageously, except in seeding and securing the crop of wheat. In answer to this I must say, that my belief is, that under this system, with a good team, less manual labor is required than under the three-field course, in preparing and seeding a crop of wheat. Having more corn land, which I hope I have before shown, required more of this sort of labor. But in securing the crop, I will acknowledge it will require a greater press; and who can object to this press, when he is so well paid for it? All this extra time we are supposed to be idle, or at least no profitable farm labor, with teams, can be imagined. I hope your correspondent will not contend that my force (which has been given) is more than sufficient to cultivate a farm of its extent, under any system, where improvement is aimed at. I am as much, or more pressed at this season of the year in preparing for corn, and getting out my manure—for he must recollect how much more the system gives in this article for employment. Upon due reflection, one must think upon the whole, the labor much more equally distributed under this than the three-field course. I have certainly never yet seen the day I had not as much to do as I could do. It has on the contrary been a matter of astonishment with me, what employment is given to the hands under the three-field course at certain seasons, (for as far as I have observed, they keep as large, or a larger force of hands)—particularly those who cultivate their corn crop almost entirely with horse-power. Their crops of wheat are light and small in harvesting and thrashing, and nothing like the quantity of land manured, compared with ours. I like to be pressed, if by this pressure I can receive a sufficient compensation for it. A farmer who always has spare, or sufficient time to accomplish any work, is sure to become careless and inattentive about it; and from this inattention, his purse and farm both become sufferers. I beg not to be understood as desiring this press, that I may impose an undue degree of hardship on the slaves; by no means—but enough to keep one always on the alert, and his wits exerted, to get through in due season.

I must beg leave to differ from W. B. H. in supposing that no corn will be sold from the four-field and fallow system. An estate well managed under that system, should sell corn enough nearly, or quite, to defray the expenses of the estate: for I have no question, but that from its improvement, it will yield from 5 to 8 barrels of corn to the acre. I am supported in this conclusion also, by the fact that my brother the last year averaged 7 barrels of corn per acre, on one-fourth of the Woods Farm in Curle's Neck, an estate which has been regularly under this system for 19 years. I have never made less than enough to support the estates, except the first year; (and this deficiency I have upon a former occasion accounted for) and might have sold corn each succeeding year, had I not had so large and expensive family. And with me it is a most extravagant and wasteful article. If I had practised the same economy in the management of my corn crop that some do, I might have been quite a considerable seller in that article. Many sell more than they should, for their teams are often not in a condition to perform their required labor. As my estate has improved greatly, I shall calculate hereafter on selling enough to pay all the necessary expenses of the estate. I should remark that my corn crop of the last year has not all been shucked out, being told that it would keep much better in this state. I therefore do not know the precise quantity, but this I will say, that, after encountering the severest drought I have ever known, it will make considerably more than the same field did when previously in corn. Dr. John Minge was an eye witness to the fact.

I greatly prefer, too, when we realize money from a farm, it should be received in as large sums as possible, to its being much divided. For my fingers, unfortunately, are too slippery for it to stick, when it comes in driblets, but, when derived in a large sum it is more apt to be appropriated to a good purpose: particularly, would I prefer it, when we can get so much more of it from the wheat crop under the four-field and fallow system.

I should mention also that I have sold corn at $1 50 and $1 75 per barrel. I would ask, how would a poor farmer feel, and in what situation would he be placed, who relied upon his corn crop, as his staple crop, for a support, those years? Of the two crops, wheat and corn, the latter is unquestionably the most uncertain and variable, both in product and price.

W. B. H. next objects to the system, because he says the succession of three white, or grain crops, is opposed to the universal practice and experience of all good cultivators of the soil, both to the north, and in Great Britain. To this I must say, that I have never had the time, and if I had, have never devoted it to reading English works upon agriculture, and therefore can say nought as to their practices. This I do know however, that our climate and soils must differ materially from theirs; and therefore the same rotation of crops may not agree. And I well know that two small grain crops, that is, wheat after wheat, or oats after oats, will not succeed well; because I suppose, the previous one has exhausted most of the ingredients contained in the earth, peculiarly suited to the second crop, and in which it would most delight. But it must be recollected that one-third to one-half of the surface will have had a manuring, besides the remaining effects of the clover, and the entire decomposition of the stubble of the first crop of wheat; and the corn crop, a hoe and summer crop, and entirely a different one in its cultivation intervening, prepares the earth with a pabulum the better suited to the second crop of wheat. It is true that the second crop of wheat is not so large a one as the first—and it would be expecting too much for it to be so, after two other crops previously—but even then, I believe it is a better one than is generally made under the old system of three-fields; and if the average is taken of the two crops it is indisputably so.

W. B. H. next says, "cannot a standing pasture be combined with the three-field course," &c. &c. I have before said that such an occurrence had never yet met my observation. Those who are impressed with the necessity of it are too reluctant to commence it, by surrendering a portion of their arable surface, (which, however, is not always necessary.) And many with whom I have conversed, are impressed with the necessity of a change of system, but cannot bring their minds to the conclusion of surrendering a larger, for a smaller portion of land for corn: for say they, "one-third of my farm, now scarcely furnishes me with corn—how then can I possibly make bread on only a fourth?" "But," it might be answered, "are you not now on the eve of starvation under your present system? Are your lands improving; or do you realize any thing from them?" "No, I sell enough corn barely to pay my blacksmith's account, &c. and of wheat, if it should be a good season, to defray my other expenses, with great economy." "But how are your children to be benefited by this? How are you enabled even to give them a liberal education, independent of furnishing them with a start in the world?—Your parents left but yourself, and you are barely enabled to live with your means, what must become of your six children?" "Why, my father and my grandfather, &c. pursued this same system, and made money with which to buy this same estate, and raised a large family." "But your ancestors lived in better times: lands were then cheap; and they had these same lands that you are now almost starving upon in their primitive state—the rich virgin soil to work upon, and from which to make money; but they have left none of its richness for you, from which to do the same? It is now a waste, gullied and barren. And what has brought it to this condition? Has it not been this same *three-field course* that you now adhere to? Has it ever been under any other? "No." "Well, by adhering to it, can your lands be improved, or your condition bettered?" "No—but before I can diminish my cultivation for corn, (which now barely supports me) I must remove to the west." Yes, sir, this is a true state of things. And this very three-field course has been the principal cause of the great tide of emigration to the west, and until that is abandoned, it must continue to flow.

W. B. H. says again—"is it not better to manure one-third with clover, under the three-field course, than one-fourth under the four-field?" Without this standing pasture I must say, there will be but little benefit derived from the clover under the three-field course. But even admitting it was not grazed off, as is customary, I question very much whether the benefits are not greater towards improvement, when turned under in the months of August and September, when it is in its greatest degree of perfection, than when ploughed under in the winter or spring, when there is scarcely a vestige of it to be seen on the land. A good clover lay for wheat may, much of it, be seen the next winter, when the same land is turned up for corn, in a perfectly decomposed state. And this fact goes a great way too in supporting the belief that one-fourth will make more corn than one-third. I have frequently when the clover has been a very heavy crop, taken up handfuls at a time remaining in this rotted state. Under the foregoing impressions, I doubt very much whether an estate would not improve the faster, when under any system the clover remained but one year. But there remains not a doubt on my mind, when, in addition to the clover, is added the greater quantity of manure.

I would remind W. B. H. and Mr. John Wickham, that it is not always the richer soil that is most successful in clover. On the contrary, we frequently see rich portions of a field fail, and poor hill-sides succeed. The soil should be freshened or altered in some way, either by manures, or by cultivation. Land which has been heavily dosed with clover, will most generally fail, if seeded in it again, before it has gone through some preparatory crop, and will become what is termed clover sick. Poor fresh land, we frequently see succeed better, and bring better clover than much richer land that has before borne it. I think our four-field system peculiarly adapted to the clover husbandry. The land from the previous cultivation, seems to be in the very best state to receive it again. I am confirmed in this fact by never having failed in my life, and if W. B. H. will observe, farms which are under this system, seem always to have better clover fields.

I hope, sir, I have said enough to condemn the three-field system as a rotation suited to us. I will briefly refer to W. B. H's. favorite system of five-fields. There appears to me to be a want of consistency in his preference for it, that I cannot exactly understand. Perhaps it is for my want of a better knowledge of it; and if wrong, I hope to be corrected. My idea of it is this: that one-fifth is in corn, two-fifths in wheat, one-fifth in pasturage, and the remaining one-fifth in clover. To be more particular, and that I may be the better understood, I will convey my idea of it by the following diagram.

	1st field.	2nd field.	3rd field.	4th field.	5th field.
1st year	Corn.	Wheat after clover	Wheat after corn.	Pasture.	Clover.
2nd.	Wheat after corn.	Pasture.	Clover.	Corn.	Wheat after clover
3rd.	Clover.	Corn.	Wheat after clover	Wheat after corn.	Pasture.
4th.	Wheat after clover	Wheat after corn.	Pasture.	Clover.	Corn.
5th.	Pasture.	Clover.	Corn.	Wheat after clover	Wheat after corn.

I have been thus particular that I may be put right, if I have taken a wrong view of the rotation. Now, W. B. H. objects to the four-field rotation, because only one-fourth is apportioned for his favorite and more valuable crop, corn. How he can reconcile this system to himself, when one-fifth only comes in that crop, (and that not after clover) I cannot imagine: for the consequence must be that his more profitable crop, corn, will be greatly lessened in quantity. Again he objects to the four-field system, because, says he, "is it not better to improve in this way one-third than one-fourth of the same farm" with clover? Under this five-field course there will only be one-fifth improved with clover. And I would ask if it is not better to improve with clover one-fourth than one-fifth? No one can doubt but that the field allotted to be grazed will be cropped harder than any. My impression is that it will be the greatest sufferer of the five fields. The idea of appropriating one-fifth annually of arable surface as a pasture, will never do. The clover if sown on the pasture field will soon be destroyed by the stock, for you must commence on it, grazing before it can have gotten much start in the spring in growing; and it is easily destroyed at that season, and if not seeded in clover lands which are regularly cultivated, throw up but little grass from which to nourish stock. The advantage of a standing pasture is, that it forms a sod of blue or other grasses, which is not killed, but increased by being trod by stock; but where you cultivate lands regularly, this sod is destroyed, and therefore your fields will be left bare and exposed the whole summer to the hoof and the sun. But there are other objections which are of too "formidable" a character to be overlooked, and which I should imagine would be serious ones with him, viz. that the field grazed would come in corn the succeeding year, and consequently that crop greatly shortened for the want of the clover. There would not only be three grain crops in succession, but what would be much worse, there would be four, or what might be considered equivalent to it—and they may be counted in this way. 1st. Wheat. 2nd. Grazing—3rd. Corn—and 4th. Wheat. So that the two latter crops will not have received any benefits from the clover whatever: on the contrary will be preceded by a bare crop, (for I know not what else to call it.) This must be the case; for the usual number of stock of all kinds kept on an estate, will leave not a vestige of vegetable matter on one-fifth of a farm, when it is kept under regular tillage, and only remains out one year. It is true you will have the stick weed, &c., which we had better be without. Again; under this system you would have less materials from which to make manure. Also, you will have more fencing to keep up; as your wheat fields must be divided from each other occasionally. The fact stated by W. B. H of his having to abandon it in consequence of its becoming too foul, is alone sufficient to condemn it with me. I am opposed to these odd rotations—for to me they appear odd, indeed. If I were to cultivate lands which would not bear the four-field and fallow system, (and I think there is but little with us that will not) I should adopt the system of Arator—and which is the system I spoke of in allusion to Mr. Lewis. Or, I should adopt the six-field until my land was in a condition to pursue the more rigid and profitable one of four-field, and fallow: but none without a standing pasture. If our lands lie out too long (which is an objection to all fallow systems with us, except the four-field,) they become too foul with blue grass, &c. &c. Once in four years in a hoe crop is almost indispensable, and therefore the five or six-field systems will not answer. If W. B. H. imagines that I recommended the four-field and fallow system for "universal adoption," he is certainly mistaken. I did so for our James River lands, and now take pleasure not only in recommending it to James River farmers, but for all farms which can be made to produce clover—as it combines the two desiderata of profit and improvement in an eminent degree, above all others.

In my allusion to the four-field and fallow system having originated with Mr. James M. Selden in Curle's Neck, on James River, I was not aware of its having been practised by any one but himself, prior to the time referred to, but have since learnt, from a conversation with him, that Mr. Harding practised it about the same time, which he was not then aware of at the time he commenced it. Nor had he ever heard of its being practised by any one else, until Major Heth brought Mr. Harding down to Curle's with him, for the purpose of obtaining his advice with regard to its management, being then thought one of the best farmers in the state. It was at this time Mr. J. M. Selden first learnt that Mr. Harding was pursuing the same system with himself. And Mr. H. advised it as the best system for Major H. at Curle's. He (Mr. Harding) told Mr. J. M. S. that he was practising it on an estate which he had purchased, and which was in a very impoverished condition, but under this system, expected in a short time to resuscitate it. I believe there is not a question about his having done so; whether he continued it to his last, or not, I cannot say—but ever since I can recollect, or took any interest in agriculture, Mr. Harding has been held up as a model, and as being the very best farmer in the state. Believe me, sir, when I say that I did not intend to deprive Mr. Harding of one iota of his reputation as the father of this system. No, none—on the contrary let me add to it, by calling it *Harding's system;* and hope it will be handed down to posterity as immortalizing his name.

But before dismissing this subject, let me say a word in support and justification of this system, as practised by Mr. Harding at Dover. Mr. Harding did not pursue the system there, with the intention of improvement, having had it on lease; and I will state a few facts, as I am credibly informed, which should go to prove it. He had no standing pasture; used none, or but little plaster; sowed clover not with the view of improvement, but for grazing—had a smaller force than was necessary for the cultivation of the estate—kept a large head of cattle, and from them derived a great portion of his profits. For I am told he kept fifty or sixty milch cows, and from butter alone sold from $1000 to $1500 annually. Now, is it expected, or could it be expected, that an estate would improve under these circumstances? I wonder W. B. H. should not have inquired more particularly into the mode of its cultivation, and the assistance given to it, before pronouncing condemnation upon the system. I have never yet seen an estate under this system that has not improved, where it has been fully carried out; and all certainly cannot be in the hands of first rate managers. But I will state a fact, and W. B. H. can easily get the same information from fountain head—that Col. Allen's estate in Curle's Neck, under the management of my brother Miles, has the last year cleared net proceeds between seven and eight per cent. upon $100,000—which is more than the first cost, and rather more than its appraisement, within the last few years—and this seven or eight thousand dollars net, has been done with forty mules, and fifty hands of all sorts, and no oxen, or scarcely any—for I think he has but eight on the whole estate. This is from an estate that has been under this, and much harder systems for the last eighteen or twenty years, but for the last six or seven years under the four-field and fallow regularly. It would be well to mention too, that from its particular situation, it is a very expensive estate, as all the pork, &c. for its use has to be purchased, which should never be done on any, if possible. The gross amount of sales from wheat and corn, were between twelve and thirteen thousand dollars. Let me inform W. B. H. too, that this estate has regularly sold from $1000 to $3000 worth of corn a year. These facts do not show that this is an "exhausting course;" but on the contrary, a very improving one. These results too are without one cent being expended in lime or marl. I could relate other instances of its great benefits, but it would be superfluous. I am already weary of reciting them, and am sure others must be of hearing them. I shall therefore take my farewell of the subject, and let my efforts, as I hope in a good cause, go for what they are worth.

JOHN A. SELDEN.

From the Rail Road Journal.

EXTRAORDINARY PERFORMANCE.

The purse of $1000 offered by Mr. J. C. Stevens to any one who should succeed in going ten miles, on foot, within the hour, was yesterday gained, *eleven seconds* within the time, over the Union Course, Long Island, by a Connecticut man, named Henry Stannard, a farmer of Kilingworth. Two others, as we learn from the Courier, went the ten miles, one a Prussian, named George W. Glauer, who did the distance in 60½ minutes—and the other an Irishman named Mahoney, who did it in 61¾ minutes.

There were at starting nine competitors, whose names and deeds are thus set forth in the Courier:

Miles.

	1st	2d	3d	4th	5th	6th	7th	8th	9th	10th
Stannard,	3	4	3	3	3	2	2	1	1	1
Glauer,	2	2	1	1	2	3	3	3	2	2
Mahoney,	1	1	5	5	4	4	4	4	2	2
Downes,	5	3	2	2	1	1	1	2	gave in.	
McGargy,	6	7	7	7	5 gave in.					
Wall,	4	5	4	4 gave in.						
Sutton,	8	8	6	6 gave in.						
Mallaro,	9	9	8	8 fell and gave in.						
Vermillye,	7	6 gave in.								

The winner did not show much fatigue, and was seen soon after riding about the Course.

The other two who went the ten miles received $200 each.

The Courier gives this statement of the time in which each mile was done by the winner:

	Min.	Sec.
1st mile,	5	36
2d "	5	45
3d "	5	58
4th "	6	29
5th "	6	2
6th "	6	3
7th "	6	1
8th "	6	3
9th "	5	57
10th "	5	54
	59	48

It is said that the course is six feet over a mile, making sixty feet more than the ten miles, in the distance run.

Now 60 feet being the 88th part of a mile, it would allow (taking the time of the last mile) four seconds, which is to be deducted, making the distance therefore in fifty-nine minutes and forty-four seconds.

The speed of the runners will be best estimated perhaps by stating, that Stannard was accompanied the whole distance by Mr. Stevens on horseback, and that the horse was all the time in a fast canter.

From the Genesee Farmer.

BEET ROOT SUGAR.

A committee of the French Chambers have made recently a long and elaborate report, on the state of their tariff, and the effect of high duties, in the course of which, the article of imported sugars necessarily led to an examination of the quantity of that staple manufactured in France.

The report "enters at great length into the state of the manufacture of beet root sugar, and brings to light a variety of circumstances respecting that description of sugar hitherto but little known even in France. It appears that this sugar, not being liable to duties in any way proportioned with those levied on the colonial article, has established a competition in the home market which is highly injurious to the importer of and the dealer in the latter. The number of manufactories of beet root sugar in various parts of France has been increasing rapidly of late years. Land destined for the cultivation of beet root is let at a higher rent than for any other production. About 18,000,000 kilogrammes, equal to 36,000,000 lbs. or 18,000 tons a year of the article are manufactured, according to the latest estimates, and the profits it yields to the manufacturer are enormous. The committee recommend that beet root sugar should be taxed in such a way as to be of advantage to the revenue, without being injurious to the interests of the colonial planter and the refiner of colonial sugar."

From Radcliff's Report on the Agriculture of Flanders.

FEEDING HORSES IN FLANDERS.

Eight horses perform the entire work of the 200 acres, and are in the highest possible condition. They are of the most compact kind of Flemish horse, and do not exceed 15½ hands, in height; chiefly roan and chestnut in color. As the banks of the river supply good hay, in this district they are indulged with that species of food, which is not the case in other parts of Flanders; but they are also fed upon straw, chiefly of rye, and upon oats with chopped straw in every feed, and *after* every feed, a bucket of water, richly whitened with rye, or oat meal. A vessel of this composition is in every stable, nor are the horses suffered to have any other drink. The quantum of food in the 24 hours for each horse, in the winter, is 15 lbs. of hay, 10 lbs. sweet straw, and 8 lbs. of oats; in summer, clover is substituted for hay; the other feeding remains the same; and the white water is never omitted: on this they place a chief reliance. The allowance of oats is but moderate, and yet the horses are in superior condition; the chopped straw contributes much to this, in converting, by the mastication necessary, every grain of corn to nutriment. The use of it is so universally approved throughout Flanders, that in every town it is sold by retail, and if generally adopted with us, it could not fail to improve the condition of the working horses, and lessen the expense of their provender.

In Flanders, a farmer will work fifty acres with two horses; and by the regularity of his care and keep, will preserve their condition. In Ireland, the great wheat farmer of Fingal, upon a similar extent, will keep four times the number, fed more expensively, but not so judiciously, always overworked and always poor. Some of these farmers, upon 100 acres, keep sixteen horses in their employ, and there have been instances of three-fourths of that number being lost within the year by hardship and disease. By these means the profits of a farm are consumed without benefit to the farmer; and what would reasonably support and enrich him, is squandered upon supernumerary horses. This special circumstance, not the high rent, keeps the tenant in indigence and difficulty. If landlords interferred to procure for their tenantry a good description of working horse, and encouraged them to use him properly, and feed him well, it would tend more to their advantage than any abatements they can give. Upon the farm of Vollandre, the management was in all points to be approved: economy prevailed in every respect, except in the application of manure; the occupier was in comfort and affluence, and yet his rent was near 40s. by the plantation acre, and his taxes triple those of the Irish farmer. The difference is to be found in established system, skilful management, and unceasing industry.

GAS USED AS FUEL FOR COOKING.

Extract from a letter of Mr. John Barlow, one of the most experienced and distinguished engineers of London, dated on the 27th February last.

"There is one source of revenue to a coal gas company, fast coming into practical effect here, which promises to be of great importance, namely cooking by gas; I know one family who have used no other fuel for cooking for the last two years, and another who for several years have never lighted any other fire in their house, for any purpose whatever, than gas, during the 3 or 4 hot months, and they both say that it is cheaper, more convenient, cleanlier and the cooking better. Hundreds, and probably thousands of families will, in this country, be supplied with gas for cooking during the ensuing summer. They now roast, bake and boil by gas. The heat is always ready when wanted, and is extinguished when it is no longer required: no dust, no preparation, nor any cleaning up afterwards; the cook can leave a joint of meat either roasting or boiling, and never look at it again till the clock informs her it is time to take it up; I know a family who regularly put their meat down, and all go to church on Sunday, locking the house up, and leaving a capital dinner to the care of the gas. I dwell on this subject a little, because in my view, it is very important, and it behooves directors and shareholders to give it every encouragement.

LIVERPOOL AND MANCHESTER RAILWAY.

The editors of the Baltimore American have been favored with a report of the directors of this work, and present their readers with a brief synopsis, from which it appears that during the half year ending on the 31st December, the receipts were,

Coaching department,	£60,292	7	4
Merchandize do.	41,197	18	6
Coal do.	3,408	16	4
	104,899	2	2
The expenses of all kinds, during the same period, were	64,552	15	7
Net profit for six months,	£40,346	6	7

The directors in former reports have alluded to the course which they had considered it expedient to adopt of substituting heavier and stronger rails in place of those which from time to time had been bent or broken; owing to the service to which they were subjected, from the speed and weight of the engines, being far more severe than was originally contemplated. From experience of the decided superiority of these parts of the way which have already been laid with the stronger rails, the directors feel the propriety of proceeding to re-lay with stronger rails such portions of the line as have from time to time to be taken up for the purposes of substituting stone blocks for the original wooden sleepers, and they doubt not, in so doing, they shall obtain the concurrence of the proprietors.

By the foregoing statement of accounts it appears that there is a net disposable profit for the half year of	£40,346	6	7
Which added to the surplus from last half year	155	11	0
Amounts to	£40,501	17	7

Of this sum the directors recommend that a dividend be now made to the proprietors of £4 10s. 0d. per £100 share amounting to £35,850. That £3000 be appropriated to the relaying of the way with stronger rails and that the remaining sum of £1651 17s. 7d. be carried as general balance to the next half year's account.

Extracts from the last edition of the "Complete Grazier."

ON THE ECONOMY AND MANAGEMENT OF THE DAIRY.

Of the making and preservation of Cheese.

The goodness of cheese, as well as of butter, depends much on the quality of the milk; though the season, and particular process adopted in making it, also, have a very considerable influence upon it in this respect—more perhaps than the material of which it is prepared. We shall, therefore, briefly notice these circumstances; and, as different modes of making cheese are practised in different counties or places, we shall then concisely state those which are more particularly deserving of notice.

The best *season* for this purpose is from the commencement of May till the close of September; or, under favorable circumstances, till the middle of October; during which interval cows are, or can in general, be pastured. In many large dairies, indeed, cheese is often manufactured all the year round; but the winter cheeses are much inferior in quality to those made during the summer months; though there is no doubt but that good cheese may be made throughout the year, provided the cows be well fed in the winter. It is also worthy of attention, that milk abounds most in caseous matter during the spring, and with the butyraceous in summer and autumn.

After milk has been exposed for a certain time to the air—generally two or three days, according to the season—it becomes sour and coagulates. The curd which is thus formed may then be either made into butter, by the process of churning, as already detailed in the preceding chapter, or, being merely broken, the serum, or whey, separates from it, and, by means of pressure, it becomes cheese. The curd thus formed, being composed of both the caseous and the butyraceous matter combined, constitutes the richest, or what is commonly termed *full-milk cheese:* that produced by the curd which remains after the cream has been taken off, is necessarily more poor, in consequence of the abstraction of the butyraceous substance, and is termed *skim-milk cheese;* but there is no material difference in the mode of making either. It having, however, been found, that cheese made from sour milk is hard and ill-flavored, means have been devised to curdle it while sweet. With this view various substances have been employed, but the most effectual hitherto discovered, and consequently the most generally used, is taken from the stomach of calves—denominated *rennet;* and, as no good cheese can be made without it, great attention is necessary in preparing it for coagulating the milk. Strictly speaking, rennet is the coagulated lacteous matter, or substance, found in the stomachs or maws of calves that have been fed only with milk, though it is, in a more extensive sense, applied to the *bait, vell, maw,* or, *stomach,* as it is variously termed, which possesses the same properties; and which is now invariably used for that purpose.

Dairy women usually preserve the maw, and the curd contained in it, after salting them, and then, by steeping this bag and curd, make a rennet, to turn their milk for making cheese. But a more simple method, and which is equally good in every respect, is to throw away the curd, and, after steeping it in pickle, stretch out the maw upon a slender bow inserted into it, which will soon be very dry, and keep well for a long time. An inch or two of the maw thus dried, is steeped over night in a few spoonsful of warm water, which water serves full as well as if the curd had been preserved for turning the milk. It is said that one inch will serve for the milk of five cows. However, as the quality of the rennet is of considerable importance, in the manufacture of cheese, we shall here mention a few of the most approved methods of its preparation. That recommended by the late Mr. Marshall is as follows:—

"Take the maw of a newly killed calf, and clean it of its contents: salt the bag, and put it into an earthen jar for three or four days, till it form a pickle; then take it from the jar, and hang it up to dry, after which it is to be replaced in the jar, (the covering of which should be pierced with a few small holes to admit air,) and let it remain there for about twelve months.

When wanted for use, a handful each of the leaves of sweet-briar, dog-rose, and bramble, with three or four handfuls of salt, are to be boiled together in a gallon of water, for a quarter of an hour, when the liquid is to be strained off and allowed to cool. The maw is then to be put into that liquid, together with a lemon stuck round with cloves; and the longer it remains in it, the stronger and better will be the rennet. Half a pint or less of the liquor is sufficient to turn 50 gallons of milk."

The above is much used in Gloucestershire. In Scotland, according to Mr. Aiton, so far from throwing away the curdled milk found in the stomach of the calves, or washing away the chyle, both are carefully preserved, and are supposed to form a more powerful rennet than can be drawn from the bag alone. It is prepared thus:—

"When the stomach, or bag—usually termed the yirning—is taken from the calf's body, its contents are examined, and if any straw or other food be found among the curdled milk, such impurity is carefully removed; but all the curdled milk found in the bag is carefully preserved, and no part of the chyle is washed out. A considerable quantity of salt—at least two handfuls—is put into and outside the bag, which is then rolled up, and hung near a fire to dry: it is always allowed to hang till it is well dried, and is understood to be improved by hanging a year, or longer, before being infused.

When rennet is wanted, the yirning, with its contents, is cut small and put into a jar with a handful or two of salt; and a quantity of soft water that has been boiled, and cooled to about 65°, or of new whey taken off the curd is poured upon it. The quantity of water, or whey, to infuse the bag, is more or less according to the quality of the yirning: if it is that of a new-dropped calf, a Scots choppin, or at most three English pints, will be enough; but if the calf has been fed four or five weeks, two quarts or more may be used. The yirning of a calf four weeks old yields more rennet than that of one twice that age. When the infusion has remained in the jar from one to three days, the liquid is drawn off, and strained, after which it is bottled for use; and if a dram-glass of any ardent spirit be put into each glass, the infusion may either be used immediately, or kept as long as may be convenient."

Rennet thus made, from the maw of a well fed calf of about five weeks old, Mr. Aiton says will coagulate thirty gallons of milk; but its chief advantage consists in the quickness with which it is performed, which he asserts does not occupy more than from five to ten minutes, while in England the same operation usually requires from one to sometimes three hours, and this he attributes chiefly to the removal of the curdled milk and the washing away the chyle from the maw, and partly to the practice of hanging up the bag to dry after it has been steeped, by which the pickle, which he considers as the best part of the rennet is lost. In opposition, however, to Mr. Aiton, an ingenious writer, who has made strict inquiry into this subject, recommends the following method of preparing a rennet, which he has found to be better than any other:—

"Throw away the natural curd, which is apt to taint and give the bag a bad smell; then make an artificial curd, or rather butter, of new cream, of sufficient quantity to fill the bag. Add three new-laid eggs well beaten, one nutmeg grated fine, or any other good spice; mix them well together, with three tea-cups full of fine salt; fill the rennet bag with this substance, tie up the mouth, lay it under a strong brine for three days, turning it over daily. Then hang it up in a cool and dry place for six weeks, and it will be fit for use. When it is used, take with a spoon out of the bag a sufficient quantity of this artificial butyrous curd for the cheese you purpose to make, dissolve it in a small quantity of warm water, and then use it in the same manner as other rennet is, mixed with the milk for its coagulation."

But, whatever kind of rennet the dairy woman may choose to prepare, it should be remembered, that this animal acid is extremely apt to become rancid and putrescent, and that great care is necessary to apply a sufficient quantity of salt to preserve it in its best state; because the rank and putrid taste, occasionally found in some of our English cheeses, is owing to a putridity in the rennet. The following mode of preserving it in a sweet state, as practised in the West of England, may, therefore, not be undeserving of attention.

"When the rennet bag is fit for the purpose, let a strong solution of salt be made with two quarts of sweet soft water, and add to this small quantities of almost every indigenous and foreign aromatic spice that can be obtained. Boil the whole gently, till the decoction is reduced to three pints, over a clear fire, if possible, or at all events, so that it may not become smoky; next, let the liquor be carefully strained, and poured, in a tepid state, upon the rennet bag. A lemon may now be sliced into it; and, after the whole has stood at rest for one or two days, it may be strained and bottled. If well corked, it will retain its goodness for a year, or even longer, and will communicate an agreeably aromatic flavor to the cheese that may be made with it."

In a case of emergency, or where no good rennet can be procured, a decoction of the yellow flowers of the *cheese-rennet*, or yellow lady's bed-straw, (*Galium verum*, L. which blossoms in July and August,) will answer every purpose for coagulating milk. Or the marine acid, in the hands of a judicious person, may be employed for this purpose as is practised in Holland. The mode of making cheeses in most general use in this country is chiefly as follows, although there are many slight varieties in the practice of different dairies even in the same counties.

Cheshire cheese. The evening's milk is set apart till the following morning, when the cream is skimmed off, and poured into a brass pan heated with boiling water, in order to warm; one-third part of that milk is thus heated. The new milk, obtained early in the morning, and that of the preceding night, being thus prepared, are poured into a large tub, together with the cream. To this is put a piece of rennet, which had been kept in warm water since the preceding evening, and in which a little Spanish annatto (the weight of a quarter of an ounce is enough for a cheese of sixty pounds) is dissolved.* The whole is now stirred together, and covered up warm for about half an hour, or till it becomes curdled; it is then turned over with a bowl, and broken very small. After standing a little time, the whey is drawn from it, and as soon as the curd becomes a little more solid, it is cut into slices and turned over repeatedly, the better to express the whey. Next the curd is removed from the tub again, broken by hand into small pieces, and put into a cheese-vat, where it is strongly pressed both by hand and with weights, in order to extract the remaining whey. After this it is transferred to another vat, or into the same, if it be previously well scalded, where the same process of breaking and expressing is repeated, till all the whey is squeezed from it. The cheese is now turned into a third vat, previously warmed, with a cloth beneath it, and a tin hoop or binder put round the upper edge of the cheese, and within the sides of the vat, the former being previously enclosed in a clean cloth, and its edges placed within the vat. These various processes occupy about six hours, and eight more are requisite for pressing the cheese, (under a press of 14 or 15 cwt.,) which, during that time, should be twice turned in the vat, around which are passed thin wire skewers, and frequently shifted. These skewers are of strong iron wire, about 18 inches long, and the vat and hoop have holes, about an inch apart, through which the sides of the cheese are skewered. Some dairy women also prick the upper surface of the cheese all over, an inch or two deep, in order to prevent its blistering. The following morning and evening it must be again turned and pressed; and also on the third day, about the middle of which it is removed to the salting chamber, where the outside is well rubbed with salt, and a cloth binder passed round it, which serves as a lining to the vat, but is not turned over the upper surface. The cheese is then placed midside up in brine, in a salting tub, and the upper surface is thickly covered with salt. Here the cheese is for nearly a week turned about twice in the day, then left to dry for two or three days, during which period it is turned once, being well salted at each turning, and cleaned, each day. When taken from the brine, it is put on the salting benches with a wooden girth round it, of nearly the thickness of the cheese, where it stands about eight days, during which time it is again salted and turned every day. It is next washed and dried; and, after remaining on the drying

* Marigolds, boiled in milk, are also used for coloring cheese; to which they also impart a pleasant flavor. In winter, carrots scraped and boiled in milk, afterwards strained, will produce a richer color; but they should be used with moderation, on account of their taste.

benches about seven days, it is again washed in warm water with a brush, and wiped dry. In a couple of hours after it is scoured all over with sweet whey batter; which operation is afterwards frequently repeated; and lastly, it is deposited in the cheese or store room, (which ought to be moderately warm, and sheltered from the access of air, lest the cheese should crack,) and turned every day, till it become sufficiently hard and firm.* They require to be kept a long time; and if not forced by artificial means, will scarcely be sufficiently ripe under two or three years, or even more. The Dutch make their cheese nearly in the same manner, excepting that they substitute the marine acid, or spirit of sea salt, which imparts to *Dutch cheese* the peculiarly sharp and salt flavor for which it has long been remarked; and that they leave out the cream.

In Mr. Holland's very intelligent Survey of Cheshire, the following remarks occur on the practice of the Cheshire dairies, from which some important hints may be gathered respecting both that and the general process of making cheese. He says, "this is generally admitted, that not only the quantity, but the quality of the curd as to texture, (toughness, or otherwise,) depends, in a great measure, on the length of time the cheese is in coming; and that the time again depends on the quantity and strength of the coagulum used, the state of the atmosphere, and the heat of the milk when put together. In this stage of the art, where a degree of accurate certainty seems to be required, there is no other guide but the hand, and the external feelings. The thermometer of a Cheshire dairy woman is constantly at her fingers' ends. Accordingly, the heat of the milk when set is endeavored to be regulated by the supposed warmth of the room and the heat of the external air; having reference also to the quantity and strength of the steep; so as that the milk may be the proper length of time in sufficiently coagulating; which is generally thought to be about an hour and a half. The evening's milk—of suppose 20 cows—having stood all night in the cooler and brass pans, the cheese maker (in summer,) about six o'clock in the morning, carefully skims off the cream from the whole of it, observing first to take off all the froth and bubbles, and the rest of the cream is put into a brass pan. While the dairy woman is thus employed, the servants are milking the cows, having previously lighted a fire under the furnace, which is half full of water. As soon as the night's milk is skimmed, it is all carried into the cheese tub, except about three-fourths of a brass pan full, (three to four gallons,) which is immediately placed in the furnace of hot water, in the pan, and is made scalding hot; then half of the milk thus heated is poured to the cream, which, as before observed, had been already skimmed into another pan. By this means all the cream is liquified and dissolved, so as apparently to form one homogeneous or uniform liquid, and in that state it is poured into the cheese tub. But before this is done, several bowls or vessels full of new milk, or perhaps the whole morning's milk, will generally have been poured into the cheese tub.

"In some celebrated dairies, however, they do not, during the whole summer, heat a drop of the night's milk; only dissolve the cream in a brass pan floated or suspended in a furnace of hot water. In other dairies, they heat one-third, one-half, or even more than that of the previous night's milk; but in all, they are careful to liquify or melt the cream well before it is mixed with the milk in the tub;* and whatever may be the general custom in any given dairy respecting the heating of the milk, the practice varies according to the weather. It is generally on poor clay lands that the milk most requires warming: on good rich soils, it will not bear much heating; at least, by so doing, the process of cheese-making is rendered more difficult.†

In making *Gloucester cheese*, as well as other kinds of thin, or *toasting-cheese*, known as the *Trent-side* and *Cottonham*, the milk is poured into the proper vessel, immediately after it has been drawn from the cow; but being thought too hot in the summer, it is lowered to the due degree of heat by the addition of skimmed milk; or, if that will not do, by pouring in water. When the curd is *come*, it is broken with a double cheese-knife, and also with the hand, to separate it from the whey which is ladled off. The curd is then put into vats, which are submitted to the action of the press for ten minutes or a quarter of an hour, till the remaining whey is extracted. It is next removed into the cheese-tubs, again broken small, and scalded with a pailful of water, lowered with whey in the proportion of three parts of water to one of whey, and the whole is briskly stirred. After standing a few minutes for the curd to settle, the liquor is strained off, and the curd collected into a vat, and when the latter is about half full, a little salt is sprinkled over and worked into the cheese. The vat is now filled up, and the whole mass of cheese turned twice or thrice in it, the edges being pared, and middle rounded up at each turning. Lastly, the cheese is put into a cloth, and, after undergoing another pressure, it is carried to the shelves, where it is turned, in general, once a day, till it become sufficiently close and firm to admit of its being washed. The only material difference is, that Gloucester and Trent-side are rather thicker than the Cottonham—which is not more than an inch and a half in depth, and is therefore sooner

* The cheese rooms in Cheshire are generally placed over the cow houses on a floor strewed with rushes. This is done, in order to afford them, from the heat of the cattle below, that uniform and moderate degree of temperature, which is deemed essential to the proper ripening of cheese.

* The practice in this respect is different in Scotland, in districts of which country the manufacture of cheese, particularly the *Dunlop*, has been carried to great perfection. There the cream, when separated from the milk, is put into the curd-vat cold, and brought, by the admixture of warm milk, to the general warmth of the mass at setting the curd. Mr Aiton is of opinion, that by melting the cream, much of the oily matter it contains is carried off with the whey, and impoverishes the cheese: but he admits that he has not had sufficient experience of that practice to enable him to decide on its comparative merit with the Scotch method.

† This although the opinion of Marshall and other celebrated writers, as well as that of Mr. Holland, is contradicted by Mr. Aiton, who says, "I never understood that the milk of cows so fed, (on poor clays, or even wild waste land, or moss,) required to be heated more than that of cows fed on the warmest valleys or richest haughs in our best cultivated districts."—*Dairy Husbandry*, p. 128.

ready for the table than the others; and that the latter is put together rather hotter than the two former.

Much of what passes under the names of *Double Gloucester*, and of *Cheddar Cheese*, is made in Somersetshire, by the following simple process:—

When the milk is brought home, it is immediately strained into a tub, and the rennet is added, in the proportion of about three table-spoonsful to a quantity sufficient for a cheese of twenty-eight pounds; after which it remains undisturbed for about two hours, when it becomes curd, and is broken. That done, three parts of the whey are warmed, and afterwards put into the tub for about twenty minutes: the whole whey is then again put over the fire, made nearly scalding hot, and returned into the tub, to scald the curd, for about half an hour, after which part of the whey is again taken out, and the remainder left with the curd until it is nearly cold. The whey is then poured off, the curd broken very small, put into the vat and pressed, remains there nearly an hour, and is then taken out, turned, and put under the press again till evening; when it is turned, and put in again until the next morning. It is then taken out of the vat, salted, put into it again with a clean dry cloth round it, and remains in the press till the following evening, when it is again taken out, salted, put into the vat without a cloth, and pressed till the next morning: it then finally leaves the press, and is salted once a day for twelve days.*

Stilton Cheese has only been introduced since about the middle of the last century. It was first made by a Mr. Paulet, who resided in the Melton quarter of Leicestershire, but who, being a relation of the landlord of the Bell Inn, at Stilton, on the great North road, supplied his house with cheese of such a singularly superior quality, that it became in demand beyond the consumption of the house, and was then sold so high as half-a-crown a pound.† It thus acquired the name of Stilton Cheese; but the mode of making it having been soon discovered, it is now generally made throughout all the neighboring counties; the sale is no longer confined to Stilton, and much of what comes to market under that denomination is of very inferior quality. Its richness depends, of course, both on the breed of cows employed, and the quality of the pasture on which they are fed, as well as upon the quantity of *cream* used in the making up; for, unless a large portion of this be added to the milk, the cheese will be deficient in all the essential qualities for which it is remarkable.

It is commonly made by putting the night's cream to the milk of the following morning with the rennet; and as soon as the curd is come, it is taken out *whole* and put into a sieve, gradually to drain. While it is thus draining, it is pressed till it become dry and firm, and is then removed into a wooden box or hoop, adapted to its size; this sort of cheese being so very rich, that it would separate or fall to pieces were not this precaution adopted. Afterwards it is turned every day on dry boards, cloth binders being tied round it, and which are made tighter as occasion may require. After it is removed from the box or hoop, the cheese is closely bound with cloths, which are changed daily, till it become sufficiently compact to support itself; when these cloths are taken away, each cheese is rubbed over every day once (and if the weather be moist or damp, twice,) for two or three months, with a brush, which is also done every day to the tops and bottoms of the cheeses before the cloths are removed. Sometimes it is made in a net like a cabbage-net, which gives it the form of an acorn. Stilton cheeses are not sufficiently mellowed for use, until they are two years old; and will not sell unless they are decayed, blue, and moist. In order to accelerate their maturity, it is no uncommon trick to place them in buckets, and cover these over with horse-dung. Wine is also said to be added to the curd, in order to produce a rapid advance of ripeness.

In making *Wiltshire cheese* (which is admitted to be among the best English sorts) the milk is "run" as it is brought from the cow; or if it be of two warm a temperature, it is lowered by the addition of a little skimmed milk. The curd is, in the first, place, broken with the hand to various degrees of fineness, according to the sort of cheese intended to be made. Thus, for *thin* cheese, it is not reduced so fine as in the county of Gloucester; for the *thick* kind, it is broken still finer; and for *loaves* it is almost crushed to atoms. But, in first breaking the curd, care is taken to let the whey run off gradually, lest it should carry away with it the "fat of the cowl." As the whey rises it is poured off, and the curd pressed down; after this it is pared, or cut down, three or four times, in slices, about one inch thick, that all the whey may be extracted, and is then scalded in the same manner as Gloucester cheese. In some dairies it is the practice, after the whey is separated, to re-brake the curd, and salt it in the "cowl;" but in others, it is taken, while warm, out of the liquor, and salted in the vat. The thin sorts are disposed, with a small handful of salt, in one layer; thick cheeses, with two handsful of salt, in two layers; and loaves, with the same quantity, in three or four layers; the salt being spread, and uniformly rubbed among the curd. In general, Wiltshire cheese is twice salted in the press beneath which it continues, according to its thickness: the thin sorts three or four "meals;" thicker ones four or five, and *loaves* five or six.

Dunlop cheese is made in the counties of Ayre, Renfrew, Lanark and Galloway, of various sizes, from twenty to sixty pounds. After the milk is brought to a certain degree of heat, (about 100 degrees of the thermometer upon an average, though in summer ninety will be sufficient, as, on the contrary, during winter, a higher degree will be requisite,) it is mixed with the cream which had been previously skimmed, and kept cool; the whole is then poured into a large vessel, where the rennet is added to it, and which is closely covered up for a short time, perhaps ten or twelve minutes. If the rennet be good, it will have effected a coagulation of the milk, which is gently stirred, when the whey begins immediately to separate, and is taken off as it gathers, until the curd become tolerably solid. It is then put into a *drainer*, (a vessel made for the purpose, the bottom of which is perforated with small holes,) and the cover of which is pressed down with any convenient weight. After it has thus stood for some time, and is pretty

* Communication in the Agricultural Survey of the County of Somerset. 3d Edit. p. 247.

† Marshall's Midland Counties. 2d Edit. Vol. I. p. 320.

dry, it is returned into the first vessel or dish, where it is cut into very small pieces by means of a cheese-knife, which is furnished with three or four blades, fixed on prongs from the handle, that cut in a horizontal direction; and it is thus turned up and cut every ten or fifteen minutes, as well as pressed with the hand until all the whey is extracted. The curd is then once more cut as small as possible, and it is then salted, by the hand, care being taken to mix it minutely with the mass. Lastly, it is put into *cheesitt*, or *chessart*, a stout dish with iron hoops, which has a cover that goes exactly into it: a cloth being placed between the curd and the vessel. In this state it is submitted to the action of the cheese-press, when it is occasionally taken and wrapped in dry cloths, till it is supposed to have completely parted with the whey: it is then laid aside for one or two days, when it is again examined; and, if there be any appearance of whey remaining, the pressure and application of cloths are repeated. As soon as it is ascertained that the whey is extracted, the cheese is generally kept for a few days in the farmer's kitchen in order to dry them before they are placed in the store, where a smaller degree of heat is admitted. While there, they are turned three or four times a day until they begin to harden on the outside, when they are removed to the store, and turned twice a week afterwards. After the cheese is cured, various modes are adopted in polishing them for sale, which are rather injurious than beneficial; nothing further being requisite, besides turning them, than to rub them occasionally with a coarse cloth, especially after harvest, because at that time they tend to breed mites.*

It is, however, worthy of notice, that the practice differs, in one material point, in the best dairies; in some of which the cream is carefully separated from the milk, while in others, the milk is allowed to cool, but thickened as taken from the cow; it being thought that, "if the milk be allowed to stand till the cream separates from it, the cream can never again be completely blended with it, or retained in the curd when set, and the cheese is poorer; and this, without great care in the management, to a considerable extent."†

Green cheese is made by steeping over night, in a proper quantity of milk two parts of sage with one of marigold leaves and a little parsley, after being bruised, and then mixing the curd thus *greened*, as it is termed, with the curd of the white milk. These may be mixed irregularly or fancifully, according to the pleasure of the maker. The management is in other respects the same as for common cheese. Green cheeses are chiefly made in Wiltshire.

Skim cheese is chiefly made in the county of Suffolk, whence it is sometimes called *Suffolk cheese.* The curd is broken in the whey, which is poured off as soon as the former has subsided; the remaining whey together with the curd, being thrown into a coarse strainer; and exposed for cooling, is then pressed as closely as possible. It is then put into a vat, and pressed for a few minutes, to extract the remaining whey. The curd being thus drained from the whey, is taken out, again broken as finely as possible, salted, and submitted to the press. The other operations do not materially vary from those adopted in other cheese-making districts, but they are more easily performed on the curd of skim milk, as it is more readily coagulated and separated from the whey, and requires less subsequent care and pressing than that of milk and cream united. The Suffolk cheese forms in general, part of every ship's stores, because it resists the effects of warm climates better than others; but it is remarkable for "a horny hardness, and indigestible quality." A better kind is made in Dorsetshire, although the only perceptible difference in management consists in its being put together cooler; for, by putting milk together hot, and immediately applying the rennet, the whey drains so quickly as to impoverish the cheese, and render it tough.

Cream cheese is generally made in August or September, the milk being at that time richer and fatter than at other periods of the year. Not having the warm season to ripen it, this kind of cheese is generally made somewhat thick, in order to preserve its mellowness. Cream cheeses are more liable than the leaner sorts to accidents, owing to chillness, or the being frozen before they become hard: for when frost once penetrates a cheese, it destroys every good quality, and generates putrefaction, or makes it become either insipid or ill tasted. Hence this kind of cheese should always be kept in a warm situation, and be particularly guarded against frost, and till it has sweated well; otherwise all the advantage of its rich quality will be completely lost.* Cream cheese is, however, in general only wanted for immediate use; and that kind commonly so called is in fact, little else than thick sweet cream dried, and put into a small cheese-vat, about an inch and a half in depth, having holes in the bottom, to allow any whey that may exude, to pass, and having rushes, or the long grass of Indian corn, so disposed around the cheese as to admit of its being turned without being handled. It is thus, that the celebrated *Bath* and *York* cream cheeses are made, when genuine; but the greater part of those commonly sold are in part composed of milk.

New cheese, as it is usually termed in London, or, provincially, *slip-coat*, is, on the contrary, an early summer cheese, which is made of new milk, and about one-third of warm water. When the whey is removed, the curd is carefully kept entire, and spread upon a cloth, to the thickness of less than an inch. It is then very gently pressed, for a few hours only, and when removed from the vat, it is covered with a cloth, and placed in a warm situation, as it requires to be brought forward immediately; the management is therefore different from that of other cheese.

These are the kinds of British cheese, and in most general esteem; the other sorts, together with foreign cheese, are both too numerous and too uninteresting to the generality of dairy-men to admit of detail. The process of making cheese is much more difficult than that of making butter; and the quality depends more perhaps on the mode of performing that operation than on the richness of the milk. The temperature at which the milk is kept before it is formed into cheese, and that at

* Farm. Mag. Vol. IV. p. 381; see also, the Ayrshire Report; and Aiton on the Dairy Husbandry.

† See the Library of Useful Knowledge; Farmer's Series, No. XII. p. 45.

* Twamley on Dairying, p. 64.

which it is coagulated, or turned into curds, are objects of the greatest importance in the management of a cheese dairy: the former ought not to exceed 55°, nor to be under 50° of Fahrenheit's thermometer; and for the latter it should be at 90° to 95°. If the milk is kept warmer than 55° it will not throw up the cream so well as at the lower degree, it is also subject to get sour and give a bad taste to the cheese; and if it be allowed to be much colder than that, it becomes difficult to separate the curd from the whey, and the cheese made from it will be soft and insipid. If the curd be coagulated too hot it becomes tough; much of the butyraceous matter will go off with the whey; and the cheese will be hard and tasteless. The thermometer should, therefore, always be employed in every dairy; and, although the servants may at first be prejudiced against it, yet its evident utility, and great simplicity, will eventually reconcile them to its use.

The greatest care should be taken thoroughly to extract every particle of whey from the curd; for no cheese will keep well while any whey remains, and if any part become sour, the whole will acquire a disagreeable flavor. Similar effects are produced by the use of an immoderate quantity of rennet; it is also apt to blow up the cheese full of small holes; and this last effect will be produced if it be allowed to remain too long on one side.

Sometimes it happens that cheese will *hove* or swell, either from some accident, or from inattention in some part of the process. Mr. Holland attributes it partly to the cows being fed on clover: he also thinks that the cracking of cheese is occasioned by the use of lime on the pasture; but these observations have not been corroborated by general experience. To prevent, as likewise to stop, this hoving, it has been recommended to lay such cheeses in a moderately cool, dry place, and regularly to turn them. Whenever any one becomes considerably swollen, it will be requisite to prick it on both sides in several places, particularly where it is most elevated, by thrusting a large awl, or pin, pretty deeply into it; repeating this as often as may be necessary. Though the pricking, it is observed, will not altogether prevent the swelling, yet it will, by giving a passage to the confined air, render it less considerable, and the cavities of the cheese will neither be so disagreeable, nor consequently so unsightly or unpleasant to the eye.

A very experienced dairyman* is of opinion, that from nine to twelve months' time are requisite to ripen cheese of any kind, if from fourteen to twenty pounds weight; and lays it down as a rule, in the process of making cheese, that the hotter it is put together, the sounder it will be; and the cooler, the richer, and more apt to decay. He also recommends the use of a small quantity of *loppered*, or sour milk, as a preventive of its rising, which is one of the worst accidents to which it is liable. It should be kept in an airy but not in a cold place, and if the moderately dried leaves of the tutsan, or park leaves, as it is provincially termed *(hypericum androsæmum*, L.;*)* or, of the yellow star of Bethlehem, *(ornithogalum luteum*, L.;*)* or, if the young twigs of the common birch-tree be placed on the surface or sides of cheeses they will—especially the tender branches of the birch—be found very serviceable in preventing the depredations of mites. It is a good practice to strew a little dry moss, or fine hay, upon the shelves on which the cheeses are laid; as, when new, they sometimes adhere to the board, and communicate a dampness to it that is prejudicial to the other side of the cheese, when turned: it also promotes their drying. At a more advanced stage they may be laid upon straw; but at first, it would sink into, and deface, the surface. To which we will add, as general maxims—that great cleanliness, sweet rennet, and attention to the heat of the milk and breaking the curd, are the chief requisites in cheese making.

[To be continued.]

From the New York Farmer.

EXTRACTS FROM AN AGRICULTURAL TOUR*

Sheep husbandry in New England.

* * * * *

Elias Taylor, of Charlemont, a shrewd and intelligent farmer, gave me some account of his operations, which I record, because the opinions and practices of observing and intelligent husbandmen, even on familiar subjects, though they may contain nothing original, are worth remembering. He is familiar with the business of fattening sheep for the market, and, as I know from the best authority, has pursued it with great success.

His general practice has been to sell them after shearing. He is of opinion that it is more profitable to buy, for this purpose, wethers than ewes. He prefers merinos on account of the superior value of the fleece; dislikes Saxony for their inferior size; and thinks merinos are kept at less expense than native sheep; chooses to buy them of different ages, and puts them in his pastures, so that he may select such as are suitable, and have them come along in succession; considers five years old as the best age for fattening; chooses to feed them moderately until a short time before he designs to market them, as he thinks they will not pay the cost of high feeding for a long time; often begins to fatten in March, sheep which he designs to market immediately after shearing. His store wethers he is accustomed to keep in the yard with his cattle, upon the orts and husks which are thrown out to them. His wethers for fattening he keeps upon rowen the first part of the season; and after he begins to feed them upon corn, he takes care, he says, not to allow them to be hungry; to feed them with regularity; and never suffers them to be disturbed. His wether sheep often give four pounds of washed wool at shearing.

He mentions an experiment in feeding swine which deserves notice. He put up four swine, and fed them with potatoes and Indian meal, at the rate of three bushels of potatoes to one peck of Indian meal. He boiled the potatoes, and while hot, mashed them with the Indian meal. He then added cold water, and left the mixture to ferment, and when it became sour, he fed his swine freely with it. He says that he never had his

* By the Rev. Henry Colman, of Massachusetts. Ed. Far. Reg.

hogs thrive so well; that they gained surprisingly well; and were fed at a small expense.

* * * * *

I found some superior and well managed farms in this vicinity on the river, [the Hoosic, in Vermont;] and an intelligent and very civil man, by the name of Wright, a deputy sheriff, as I afterwards learnt, and a farmer, at whose house I stopped, was kind enough to give me considerable information of the agriculture of this part of the country. My attention was arrested by the appearance of a small field, covered with the thickest mat of white clover which I had ever seen. I stopped to inquire if it had been plastered, and found this to be the fact. Plaster, or gypsum, is applied to their oak lands with great success; but not with equal advantage to lands where the growth was maple. For this fact, if indeed it be well established, I do not pretend to account. The mode of operation of this extraordinary manure or vegetable stimulant, is still enveloped in mystery. No theory of its operation, though many plausible ones are given, has yet satisfied me. Facts are all that we have as yet got that are of any value. There is every where, in all the processes and operations of the material and intellectual world, a limit beyond which human sagacity cannot penetrate; and from which, however bold and persevering its efforts to pass may be, it is invariably driven back with the humiliating consciousness of its own impotency and ignorance. The grass and oat crops were highly luxuriant; and making due allowance for the extraordinary season, (1832,) Indian corn appeared remarkably well. The haying season had just commenced. The grass was principally herds grass and red top. The crop appeared heavy; they mowed, however, only once, as they were accustomed to feed their meadow lands closely and very late in the season, oftentimes into June, which, upon the whole, they deemed a bad practice; and they were of opinion they should get more hay by two mowings.

Large crops of oats and corn might be obtained by different management. The crops were estimated by Mr. Wright to average thirty-five bushels of oats, thirty-five bushels of corn, and two tons of hay to the acre. This, however, was probably only a conjectural estimate, as few farmers ever take the pains to weigh or measure any thing. Their produce is applied chiefly to the feeding of sheep. The yearly expense of keeping a sheep is estimated at one dollar. This likewise must in general be mere matter of conjecture. It can only be accurately determined by a careful estimate of the actual value of hay and grain; and not their market value, but their value consumed on the place, making due allowance for the valuable returns of manure; and there must enter into the estimate the labor of attendance, the value of pasture land and fencing; and then, too, a careful ascertainment of the amount of pasture required for, and the amount of hay and grain consumed by a sheep, and necessary to his profitable condition. Now these are calculations into which few farmers have the patience to enter; and one dollar per head is therefore only a conjectural estimate of the cost of keeping a sheep, formed from no accurate standard; and you can only infer from this statement, that they find their husbandry profitable, or yielding a satisfactory return at the close of the year, when they can receive for the pasture occupied, and the hay and grain consumed, by a healthy sheep, the value of one dollar. It has been found by actual experiment, that seven healthy sheep will consume one ton of hay in 135 days, the average of our winter foddering—or a little more than two pounds each per day. If we value this hay at six dollars per ton, and this is certainly, considering the cost of labor, a low price, the cost of the hay consumed by each sheep would be 85 cents. We have then about 33 weeks of pasturing to provide for, which cannot be rated at less than one and a half cents per week—or say 50 cents—which would make the keeping of a sheep, even at low rates, equal to one dollar and thirty-five cents per year. I make these calculations to show how careless almost all conjectural estimates are in matters of this kind. Whether however, his pecuniary estimates are critically exact or not, if the farmer at the close of the year is satisfied with the balance of his receipts over his expenditures, if he is so fortunate as to find the balance on that side, he may be well contented with his numerous privileges and blessings, though his gains in arithmetical amount may seem small compared with those of other trades and professions.

The amount of wool obtained from their sheep averages about three pounds of fine, their sheep being principally of the merino and Saxony race; and sold this year at 42 cents per lb. A Mr. Wright, neighbor of the one above named, has a flock of 700. His annual loss by disease or accident is a very small per centage, which he attributes to the circumstance of his never housing his sheep at any season, as he was formerly accustomed to do. His opinions and experience in this matter are entirely at variance with the opinions and experience of many distinguished and successful sheep farmers; and especially of one, whose authority on this and various agricultural subjects, from his experience, education and intelligence, is entitled to great respect; I mean Mr. H. D. Grove, of Hoosic. He says, "shelter against the inclemency of the weather is almost as necessary to the health and good condition of the sheep as food itself; and for this reason stables built for that purpose are of great benefit. Not only do sheep do much better, but it is also a great saving of fodder and manure." Mr. Wright's lambs are yeaned in May. His wool is sold on the farm. The general appearance of this farmer's grounds and crops attracted my particular attention as highly creditable. The intervals furnish abundant crops of hay and grain, and the neighboring hills afford pasturage in plenty of the best quality.

* * * * *

Comparative value of different kinds of corn—what crops to manure.

* * * The corn cultivated here [near Stillwater in New York,] is of the eight rowed kind; rather a small ear; and though not white, yet not of that deep yellow which we sometimes see. This corn was recommended for the small size of its cob; but I am disposed to believe, from some careful examinations, the results of which were communicated to the public through the columns of that admirably conducted journal, the Genesee Farmer, that the weight of cob in the different varieties of corn will be found to bear a pretty equal

proportion to the weight of grain upon it; and in this matter, therefore, the small will be found to have no advantage over the large ears. I speak particularly of the flint corn, having made no examination of the gourd seed varieties, where I suspect the advantage will be perhaps more in favor of the large ear. There is however one advantage on the side of the corn with a small cob, which deserves much consideration. The corn with the small cob is more likely to be dry and sound, and becomes merchantable earlier than that with a large cob. The large cob retains its moisture much longer; and where the season is backward, or the corn late, or where it is harvested by being cut up at the bottom while the stalks are green, and ripened in the stack, there is danger, especially if the season be unfavorable, of its not drying sufficiently, and of its becoming mouldy in the bin. I have known serious losses to accrue from this circumstance, especially where the corn after being husked had been placed in large heaps, and the granary not well ventilated. This, in fact, is the only objection I have to what is called the Dutton corn, so much commended by Judge Buel, and of which he has exhibited at the agricultural shows some splendid samples; and also to other twelve and fourteen rowed varieties. This circumstance, as I have recently learned, has induced some very intelligent farmers in New Hampshire, on the Connecticut river, to give up the cultivation of the Dutton corn for the eight rowed varieties. The large twelve rowed corn will, I believe, produce ordinarily more bushels to the acre than the small eight rowed corn. A good sized ear of the twelve rowed will yield more than half a pint of shelled grain; one of the small eight rowed will not exceed a gill. A field of the twelve rowed will yield generally one good ear to a stalk; a field of the small eight rowed will do no more; for I have not found, in my own cultivation, that the eight rowed is more likely to produce two ears to a stalk than the twelve rowed. Its producing two ears in either case, depends, in my opinion, something upon the selection of seed from twin-bearing stalks, but more upon wide planting; as corn which is crowded or closely planted will very rarely produce more than one good ear to a stalk; if there is a second, it is commonly imperfect, and a mere nubbin. It is obvious, then, that the twelve rowed corn will yield more than the eight rowed to the acre; but it will not yield twice as much, because the small kind will bear much closer planting than the large kinds, as the stalks and leaves are not nearly so luxuriant. The kind grown in this part of the country was remarkable for its low growth, and the ears being set very near to the ground, the stalks being in this case small, the fodder is more easily saved, but the yield of herbage is much less to the acre. It may be expected on this account to ripen earlier. The small amount of stalks and leaves is, I believe, attributable to their not manuring their corn lands, rather than to any peculiarity in the kind of corn. That high manuring in the same year of planting the corn will produce a great amount of stalk and leaf, is well known; but that the actual yield of grain is always in proportion to the luxuriance of the plant, is a point not so well established, and upon which I should be extremely glad of the opinions of observing and practical farmers. That the extraordinary luxuriance of the plant will delay the ripening of the grain is certain. Market-men near our large cities understand this, as they never manure the peas which they wish to bring forward very early; and it is a common observation, how well founded I will not say, that the very high manuring of potatoes causes them to "run too much to vine;" and the quantity of potatoes in the hill is not always in proportion to the luxuriance of the tops.* Whether in such cases, if the season were long enough to admit of the perfect maturity of the plant, the yield of grain and of tubers would not correspond with the great luxuriance of the herbage or stalks, is another query which grows out of the subject, and deserves inquiry and attention, as it is a matter of great practical importance to ascertain, if possible, (which can only be done by long observation and experiment,) to what degree corn, potatoes, or other plants, may be safely and advantageously forced by manure, with a due regard to the actual return in grain or tubers. I have spoken above of the small varieties of the eight rowed corn, though not of the smallest. The Hoosic corn is larger than what is called the Canada corn, though probably it is the same, and has acquired a larger size from successive planting in a lower latitude. The ear is about ten inches in length. A kind of eight rowed corn is grown on the Deerfield meadows, which frequently measures sixteen inches in length, and from a single ear of which I have sometimes obtained a full pint of grain. It ripens late, however, and requires early and very wide planting. On our fine alluvions, with high manuring, it yields about fifty bushels to the acre. It weighs from fifty-seven to sixty pounds to the bushel, whereas, my twelve rowed and a small eight rowed corn, which I have grown upon a thin soil, weigh from sixty to sixty-four pounds per bushel.

Another inquiry connected with this subject deserves attention. Is the color of the corn any index of its nutritious properties? This is a subject for experiment, and for chemical analysis. Between the varieties of the yellow and the white flint corns, I have made no experiments. The prejudices in favor of the one or the other in different parts of the country, where the one or the other is cultivated, are strong, and as in most other cases exactly coincident with the interests or habits of different individuals; those who grow and eat the yellow pronouncing the white tasteless, and those who grow and eat the white, with the same self-complacency, disdaining the yellow. But between the yellow flint of the northern states, and the white gourd seed of the south, I am inclined to believe there is a difference in nutritious properties in favor of the former. This opinion is formed only on a single experiment, which I made some years ago; but of which I preserved no written record, and can only state it from memory,

* These views accord with the reasons given in a former No. of the Farmers' Register, (p. 257, Vol. I.) in favor of applying manures, in preference, to those crops in which general bulk is wanted, instead of those of which the quantity of seed is the object—or, for example, to the crops of grass, in alternate husbandry, rather than to the wheat or corn which follow them.—Ed. Far. Reg.

and therefore not with that minute accuracy which I should desire in all such cases to observe. I had a cow, which I put in the barn in October; fed her abundantly with hay, and gave her four quarts of meal per day of the yellow flint corn; saved all the milk, and weighed her produce in butter, which during the week was nine pounds. The second week her feed was the same as before, excepting that the meal given her was the meal of the white gourd seed, or what goes among us by the name of Virginia, or southern flat corn. Her produce this week in butter fell short of eight pounds. The third week I fed her as before in quantity, and returned again to the meal of the yellow flint corn; and her produce in butter was as the first week, nine pounds. I took the exclusive care of her myself during the time, and can assign no cause for the difference in the product but the difference in the quality of the meal. There may have been other causes, however, and I by no means regard a single experiment as decisive on this or any similar subject. The meal in the several cases was measured, but not weighed; the actual quantity given, therefore, though it appeared the same, might not have been the same; and I record the experiment because I deem all such trials, where all the circumstances connected with them are detailed, of some value; and in the hope that it may induce others to make similar experiments in other matters as humble; for which experiments, if they speak of them, they may get nothing from their overwise neighbors but the sneers of real ignorance, indolence, and self-conceit, the usual attendant of ignorance and indolence, but from which they will derive themselves much pleasure and satisfaction. They are attended with little trouble or expense, and from them, in some cases, the most important results may be obtained.

* * * * *

The land, as I approached the Hudson, became thin, and strongly predominating with sand, though favorable to Indian corn, and well suited to the renovating influence of clover and gypsum; that beneficent operation by which much of the land in Columbia county, in the neighborhood of Kinderhook, has been converted from pine barrens into highly productive fields; and according to the interesting and gratifying account of Mr. Teunis Harder, given in the Quarterly Journal of Agriculture, Vol. I., No. 1, p. 32, has actually raised the value of these lands from three to sixty dollars per acre.* Nearer the river the character of the soil became much better, and within a mile of the ferry I found a superior farm, in high cultivation, belonging, I have since been informed, to a Mr. Knickerbocker. The corn crops here were very promising. I have since passed this farm, and its condition is highly creditable to its owner. I have seen, too, in this neighborhood, a herd of uncommonly fine swine; indeed, for store hogs, as many together, I have seen none superior in appearance.

* * * * *

I crossed the Hudson at this place in a ferry boat impelled by a horizontal wheel, moved by two horses. The horses had been several years attached to the boat, and though unable to see the shore, they measured the distance with great accuracy, stopping of their own accord at such a distance before they reached the shore, that the impetus which the boat had already received was nearly sufficient to carry it to the land, and when ordered to start again, turning it only one revolution and stopping again without direction. I could not help wishing that men were half as tractable.

* * * * *

Earl Stimson's Farm.

A principal object of my journey soon presented itself at a distance of two miles, which was the farming establishment and residence of Earl Stimson, Esq., whose dwelling house and numerous out-buildings, placed on a commanding eminence, had more the appearance of a village than the domain of a private individual. His buildings consist of a spacious dwelling house, with extensive piazzas in front, several barns and stables, very extensive sheds, a large store, a three story building for a granary, cider house, &c.: a large slaughter house, cooper's shop, potash establishment, blacksmith's shop, and smaller dwelling houses, which, with the fame [farm?] connected with them, had come into his possession, and might now be said to form a part of his domicil.

The situation, being at the rectangular junction of two large roads, was favorable to the prosecution of his business as an extensive trader, and the keeper of a large hotel. The homestead includes about seven hundred acres, two hundred of which are in wood; and the rest in meadow, pasture, or under the plough. He has himself favored the public with an account of his management and cultivation, in his address to the Saratoga Agricultural Society; and an exact and detailed statement of the produce and course of crops of a certain portion of his land is given by Dr. Steele, in his survey of the agriculture of Saratoga County, in New-York Memoirs of Board of Agriculture, Vol. II., p. 69. I shall, however, detail from recollection the accounts which I received from himself; and record such remarks as suggested themselves on the premises.

The soil is generally of a dark loam, resting upon sandstone and carbonate of lime. The analysis of this soil, as given by Dr. Steele, is subjoined:

Water,	9.5
Animal and vegetable matter,	12.5
Alumine,	17.5
Siliceous sand,	54.
Carbonate of lime,	3.
Soluble salts,	1.
Oxide of iron,	1.
	98.5
Loss,	1.5
	100.

The great roads passing through the farm, and crossing at its centre at right angles, give a straight line to all the outside fences; and the fields, every where divided into rectangular lots of eight

* This account was first published in the Farmers' Register, (p. 544 Vol. I,) and we presume was copied into the work to which it is credited above—which however we have not seen.—Ed. Far. Reg.

or ten acres, are enclosed by stone walls, formed of small stones gathered from the land, and surmounted by posts and two rails. The cultivation exhibited an exemplary neatness, as in but a single instance did I remark any weeds or briars growing near the fences; and these had been recently mowed.

Mr. Stimson is highly systematical in his farming, and pursues a determined rotation of crops, beginning usually with wheat, then corn, barley, clover, and herds grass two or three years; then frequently depastures his fields for one year, after which they are again subjected to the plough, following the same rotation as before, excepting that corn is sometimes a first crop after the land is broken up; and flax sometimes takes the place of corn or barley in the rotation.

He manures his land once only in six years, excepting the application of plaster to his corn. He allows five loads of barn manure, and three of leeched ashes, to an acre; and this is always spread upon the surface after ploughing for the first crop and either harrowed or ploughed in by a very light ploughing. In ploughing, he never permits the plough to go deeper than three inches; the sod is turned over flat, and then rolled, it being his great object to keep all the vegetable matter on the surface. In the ploughing for the second crop in the rotation, the sod being completely decomposed, is turned, and affords a fine soil for the ensuing crop. Though a good deal of the manure is in this way lost by evaporation, yet he considers this loss as much less than that which is occasioned by burying it under the sod. He deems leeched ashes a most valuable manure, and much to be preferred to that which is unleeched, which he considers as having a tendency at first to force the land, but in the end to impoverish it. Next to leeched ashes, he deems lime the best manure for land. The opinions of so intelligent, experienced, and successful a farmer, are certainly entitled to the highest respect, and we shall not undertake to theorize on the subject; but the subject is still matter for experiment, and deserves the most careful and philosophical investigation.

Wheat is generally the first crop in the rotation, in which case it is usually sowed in the autumn; and harrowed in at the rate of two bushels to the acre. His average crop is from thirty to forty bushels per acre. This year (1832) he has sixty acres in wheat. Of Indian corn, his average product is about five thousand bushels. He assured me that for the last ten years it had exceeded the average rate of one hundred bushels to the acre. He plants an eight rowed kind, with a small ear, on the ground where he has had wheat, in hills two feet eight inches apart each way; the places of planting being accurately marked out by a simple machine with four teeth, like a rake, and drawn by a horse, which marks the piece to be planted in one direction, and then crosses these marks at right angles. Four stalks only are left in a hill, and it is ploughed slightly, or harrowed twice. Sometimes plaster is applied to the hill, at the rate of about five pecks to an acre. He is of opinion that too much manure may be applied for any crop excepting corn. This cannot be manured too highly. Owing to the unfavorableness of the season, his corn, much of which had been planted twice, seemed quite small, and in his opinion would hardly yield him a third of the usual crop.

Potatoes are planted by him at the same distances as his corn, and on the outside of his cornfields. At the second hoeing of his potatoes, he takes pains to open the top of each hill with the foot, and to put a hoefull of dirt directly on the centre, by which means the sun is admitted to the potatoes, which he deems likely to contribute very much to the increase of the crop. This simple operation is in accordance with Mr. T. A. Knight's lately broached views of the great importance of light and air to the productiveness of the potato crop; but in a partial experiment, I have not myself perceived any sensible advantage from it. His average yield of potatoes is about five hundred bushels to an acre; and he raises yearly about two thousand bushels.

Flax is likewise a valuable crop, of which he calculates to obtain at least twenty bushels of seed, and four hundred pounds of flax; commonly more than this. His flax fields, which he was then pulling, with a platoon of sixteen men, exhibited a most luxuriant growth. After the flax is pulled and rotted, he has it cleaned and prepared for market, for two and one-half cents per lb. What he usually obtains over six cents per pound for flax, will pay for the cleaning of it. He is of opinion that it will do to repeat flax on the same land once in six years. Barley, or rye is another crop in his usual rotation, and ordinarily follows corn. Barley he considers as much the best crop with which to lay down his land to grass.

His plan of laying down his land to grass is to sow the grass seed at the time he sows his barley, at the rate of 3 lbs. of clover seed, and 4 quarts of timothy or herds grass. His crop of grass averages about two and a half tons to an acre. He feeds many of his mowing fields until the 10th of June. His grass, as I saw it, was quite ripe, and farther advanced than we are accustomed to have it at the time of mowing; and this, perhaps, accounts for his practice of cutting his grass in the morning, and housing it at night of the same day, which he informed me he frequently did. The proper time of cutting grass, as with reference to their nutritive properties, is a subject which has not received all the attention which it deserves. According to chemical analysis, some grasses are much more nutritive after their seed is perfected, than when cut in the flower. It is the reverse with other grasses. In respect, for example, to timothy or herds-grass, (Pheum pratense,) according to Sinclair's table annexed to Davy's Agricultural Chemistry, it is said that "the nutritive powers of the straws simply therefore exceed those of the leaves in proportion as 28 to 8; and the grass at the time of flowering, to that at the time the seed is ripe, as 10 to 23; and the latter math to the grass of the flowering crop, as 8 to 10."

Mr. Stimson mows his grass land usually two years; and pastures it the ensuing year. This completes his rotation of six years, and he then begins the same course again. Thus,

1, Wheat—manured.
2, Corn—plastered.
3, Flax, rye, or barley.
4, Clover and herds grass.
5, Clover and herds grass.
6, Pasture.

His potatoes are usually planted round his corn fields, three or four rows on each side, so as to render it convenient to come out with a horse, and turn the plough. He puts one large or two good sized potatoes in a hill. He steeps his seed corn before planting, in a mixture of $\frac{1}{4}$ lb. of saltpetre, to 3 pints of water; and then rolls the seed in plaster.

He purchases large numbers of cattle in the fall; those which are in condition to kill, he slaughters and packs; and it is then forwarded to the New York market, where it is repacked, inspected, and fully salted, at the expense of 75 cents per barrel. The cattle not in condition for beef, he winters, and disposes of the next spring and autumn.

He kills and packs great quantities of pork, and bacons the legs. For packing his beef, he uses four quarts of salt, with some saltpetre; and for his pork, fourteen quarts of salt to each barrel, which he deems sufficient to keep it until it is repacked in New York. He considers this a better mode of disposing of his pork and beef, than to send his cattle on the hoof, or his pork unsalted, to market.

His preparation for his hams is 4 oz. saltpetre, 4 qts. of salt, 1 pint of molasses, 1 oz. of pearlash, to 100 cwt. of meat. They are to be smoked three weeks with maple or walnut wood. Recently he slaughtered twenty hogs, whose average weight was 414 lbs. each. His hams are preserved by being sowed in paper, or coarse bags, whitewashed, and suspended in his storehouse. He has at present 700 sheep, which he considers as a profitable stock. He has thirty cows. He has paid little attention to the improvement of his stock, selecting his cows from the numerous droves which he purchases for feeding or slaughter. He never puts his young cattle in the barn. He has large and commodious sheds for their protection; and he would always choose to have wooden floors in the sheds for them to lie upon. He chooses to keep his different kinds of stock separately from each other: his milch cows in one yard, his young cattle in another.

With his laborers he always makes a written agreement, stipulating to board them, but furnishing no ardent spirits; and requiring of them good manners and good temper; early rising; a readiness to assist in husking in the evening, and to do any extra job which may be customary on a farm; and an attendance upon public worship in their turn.

Such were a few hasty and cursory observations which occurred to me in a short but highly gratifying visit to his interesting and instructive establishment; and I beg leave to express my grateful sense of the kindness and hospitality which I received, and the politeness with which the information I sought was communicated to me. In extent, in productiveness, or in its admirable management, I have seen no individual establishment to be compared with it. In extent, I except the magnificent farm of Mr. Wadsworth, in Genesee, which is confined to grazing, and where, a few years since, for it is some time since I had the gratification of visiting it, not a bushel of wheat was raised. As a dairy farm, likewise, that of Mr. Bussey, at Hoosic; and the grand establishment of Robert Smith, Esq., near Baltimore, where one hundred cows were soiled, are likewise before it; but I speak of it in respect to the variety of its business, cultivation, and products: and the skill, system, and success, displayed in its management.

Mr. Stimson has peculiar advantages in his abundant capital: in the profitable consumption of a large amount of his produce by means of his hotel, which is much frequented; in a most abundant supply of manure from his stables, slaughter house, piggery, and potash establishment; and in his facilities for procuring labor. But I saw no part of the process of his farming, which may not be copied by other farmers, on a smaller scale; and, especially as he does not apply a larger amount of manure to an acre than what is applied in other cases by many farmers.

The great points of difference between his own and the management of other farmers, and almost all other farmers, deserve particular attention. They consist, first, in the regular arrangement of his lots, which are all laid down upon a plan; and the management of each pursued systematically; and made matter of exact record.

Secondly, in his shallow ploughing, by which the vegetable mould is always kept in its proper place; or what he says, nature teaches is the proper place, on the surface.

Thirdly, in the incorporation of the manure with this vegetable matter, instead of burying it amongst the gravel or loam.

Fourthly, in his exact and systematic mode of planting; his corn being as regularly deposited as straight lines can make it.

Fifthly, in his economy of labor, his ploughing after breaking up the green sward, which is done by two horses, always being performed with one horse to a plough. He informed me that the last spring, with eight horses, he set eight ploughs in operation.

Sixthly, in his pursuing with each piece of land a regular rotation of crops. In this way the land is taxed but once in six years for the particular qualities in the soil, demanded by each particular crop; and by being three years in grass and clover, a new supply of vegetable matter is left upon the surface, to be turned under for its improvement, preparatory to a second rotation.

His ploughs are an improvement upon the Scotch plough, and of very easy draught. Of other utensils, I remarked none of a peculiar construction. He has a superior cider mill, and made last year from his farm five hundred barrels of cider. He has contrived a saw to go by horse power, with which he says two men, a boy, and a horse, are able to saw thirty cords of wood per day for the fire.

His men breakfast at six o'clock; dine at 12 M.; and sup when work is done at night. A large party of them were at work in the field nearly a quarter of a mile from the house, pulling flax, soon after 4 o'clock in the morning. He furnishes them a luncheon of bread and butter, or bread and cheese, in the field, at 10 o'clock, A. M. and 4 o'clock, P. M. Their drink, consisting of cider, cider and water, molasses and water, milk and water, is carried to them in the field. Above all, his farming, as well as all other of his operations, are under his constant and immediate supervision. To the inquiry, who was his foreman, his answer was, that he had no foreman; he was his own foreman. To every man was assigned his proper task, which he was expected to perform, so that the responsiblity rested upon himself alone; and under this conviction, he was the more likely to be faithful. I quitted the place with a just admiration of its extraordinary management, and not without a deep surprise at the system, skill, care, and success, with which such heavy and various concerns were carried on, and a press of business maintained and conducted, under which ordinary men would have been overwhelmed and confounded; the cumbrous and complicated machinery making its gyrations and movements without dislocation, without friction, and without any sensible concussion or jarring of the moved or the moving body.

Extract of a letter to the Editor of the Rail Road Journal.

SWIFT CANAL BOATS—STEAM CARRIAGES ON COMMON ROADS.

When at Glasgow I visited the "Paisley" and the "Forth and Clyde" canals; and as our country is very much interested in canal navigation, some memoranda relative to the *swift passage boats* on those two canals may not be uninteresting to your readers.

First, of the "Paisley canal," which has been the longest known, and is still most successful as regards quick travelling. This canal commences at Glasgow, and goes through Paisley (eight miles distant) to Johnston, where it terminates; 12 miles long; no lock in the whole distance. The boats are of iron, of one-sixteenth of an inch thick, 70 feet long, five feet nine inches broad, and weigh 16 cwt. 14 lbs. This is the weight of the iron part alone. The total weight of the boat, including the wood work, (the cabins are of this material,) fixtures, &c. is 33 cwt.; and with 100 passengers, draws 19 inches aft and 18 inches forward. Two horses draw the boat in stages of four miles each; the pair of horses go only 12 miles per diem. There are four boats, which make six journeys each, or twenty-four journeys for the whole, each day. These boats have been running four years. They are generally full. They meet the greatest encouragement, and are very profitable to the proprietors, notwithstanding the fare is so very moderate. The charge is six pence, in the after cabin, and nine pence in the forward, to Paisley, eight miles; to Johnston, 12 miles, the charge is nine pence in the after cabin, and 12 pence in the forward cabin. The time usually employed between Glasgow and Paisley is 50 minutes; or $9\frac{3}{5}$ miles per hour. This is the narrowest canal I ever saw, generally 30 feet wide and five feet deep. The captains of the boats on board of which I travelled, told me that on a narrow canal, such as this, the horses can pull a boat easier, *when travelling rapidly*, than on one of greater section. This, paradoxical as it may appear, is verified by the fact, that on the "Forth and Clyde" canal which is of nine feet depth, and 68 feet breadth, the boats, which are of nearly the same dimensions (68 feet long, and $5\frac{1}{2}$ feet broad,) as those on the Paisley canal, are drawn by three horses, with 70 passengers on board, and yet travel at about the same velocity as on the narrower and shallower canal. I asked these captains, and also a civil engineer of some eminence, whom I met on board, returning from Johnston, how they could account for this circumstance. Their reply was as follows: on a narrow canal, say 30 or 40 feet wide, the boat passing swiftly through the water, throws the wave against the shore, which being thrown back again against the boat, raises it up, and thus propels it. The wave strikes the boat about two-thirds of its length from the bow. But if the canal were much wider, the boat would pass by before the *reflected wave* could reach the boat, and thus give it aid. I give this explanation nearly in the words of these captains, and am responsible only for the correctness of the report of what they told me. I hope this will meet the eye of our distinguished countryman, Gen. C. F. Mercer, chairman of the Committee of Internal Improvements in the House of Representatives, who advocates with so much ability *broad* and *deep* canals for transportation, as far more economical than narrow canals. I will now finish what I have to say respecting the fast travelling on the "Forth and Clyde" canal.

This canal, as I have said above, is 68 feet broad by nine feet deep, and the iron boats are 68 feet long and $5\frac{1}{2}$ feet broad, and when light draw eight inches water, but with 70 passengers draw 20 inches; this is when in a state of rest—when in rapid motion they draw less. There are three horses employed to each boat, and the passengers who get into the boats at Port Dundas (Glasgow) are set down at Port Hopetown (Edinburgh) in $6\frac{1}{4}$ hours, a distance of 56 miles, or nearly nine miles per hour. It is necessary to explain to you that the passengers go only a part of the distance on the "Forth and Clyde" canal. They start from Port Dundas and go to Port Downie, (the commencement of the "Union Canal,") a distance of $24\frac{1}{2}$ miles, which includes four locks. In the next half mile are eleven locks, which are avoided by the passengers being conveyed in omnibuses to boats in the "Union Canal," which carry them on a level of 31 miles to Port Hopetown (Edinburgh.) I regret that I did not take a memorandum of the cost of these iron boats, which are light and beautiful vessels, and being fearful of making a mistake I do not quote from memory. On the Lancaster, Carlisle, and Kendal canals, there are rapid boats, but not having travelled by them I do not give you any details. But if any of your readers feel an interest in the above remarks, and wish further information, I can with facility procure it, and will with pleasure communicate it to you.

Since my return from the north I have called on Mr. Hancock, in company with Mr. T., one of the engineers of the Boston and Providence Railway. We found that for the last two months the "Era" and the "Autopsy" have discontinued running, owing to the absence of Mr. Hancock in Ireland, whither he went with the "Era," for the purpose of ascertaining if he could profitably introduce locomotives on the roads of that country. He is now returned to London, and will, I am informed, recommence running these two engines on the metropolitan roads in a few days. Mr. T. and I also went to see Mr. Russell's steam carriage, recently arrived from Glasgow, which will in a few days ply regularly, in conjunction with others of this gentleman's make, between Hyde Park Corner, and Hammersmith (the commencement of the great western road out of London.) This carriage is by far the most tasteful of all the steam carriages I have seen. It is built exactly like the stage coaches of this country, except the dimensions are larger. The whole of the machinery is in the hind boot. The water and the coke are in a *tender*, or separate carriage on two wheels, behind the locomotive. This steam coach will carry six inside passengers sitting *viz-a-viz*, 14 outside on the roof, and six on the tender; total, 26 passengers. From the favorable terms in which I have heard Mr. Russell's engine spoken of, both here and in Glasgow, I feel a great curiosity to ride on it, and I will take advantage of the first opportunity to do so, and will report to you respecting it, as well as others which will no doubt be introduced as the spring advances. You may inquire, why did not Mr. R. remain in Glasgow? I will reply in nearly the words of the gentleman who showed us this carriage. He said the prejudice against it was great, in consequence of the unfortunate accident by which 12 or 13 passengers were killed or wounded; that it was expedient to come to a distant part of the country. He told us, that for several months this engine plied between Glasgow and Paisley, and performed in a manner to give entire satisfaction; and in consequence, the stage coach proprietors and trustees of the road were alarmed lest this and others would gain so much in public estimation as to become regular coaches. They therefore resolved to drive it off, if possible. This they accomplished by *picking up* the turnpike, and putting fresh metal down in unusual and extraordinary quantities. Notwithstanding the road was made almost impassable, the engine was still continued, and plied regularly several times each day for a whole month, and excited the admiration of all intelligent persons, that it *could* overcome such difficulties. It however was finally injured by being driven for so long a time over a *road so much worse than it was constructed for*, and one of the hind wheels getting into a hole (made by order of the turnpike proprietors,) it broke, and the carriage tumbled to the ground; four or five persons were killed, and eight or nine others seriously maimed and wounded. But none of them were hurt from the explosion of the engine, or the escape of steam, but from being thrown with great violence against the rough, new mettled road—the same kind of injury as would be received from a common stage coach breaking one of its wheels when travelling rapidly. I am informed that an action is brought by the owners of the steam carriage, as well as by several of the survivors and the friends of the deceased, killed by this melancholy event, against the road company, for obstructing the King's highway, and causing the injury and death of a number of persons, besides loss of property. Sanguine hopes are entertained that the guilty will be severely punished.

I forgot to tell you above, that the swell on the two canals, caused by the quick passage of the boats, is very inconsiderable.

I am, very respectfully,

Your obedient servant,

GERARD RALSTON.

P. S. The demand for railway locomotives is very great. I am sending nine to different parts of the United States, and both Mr. Robert Stephenson and Mr. Bury have orders to give them full employment for several months to come.

MEMOIR ON THE MAKING OF WINE IN THE CANTON OF MARCILLAC.

By M. Charles Girou de Buzareingues.

Translated for the Farmers' Register, from the *Annales de l'Agriculture Francaise.*

The vintages which continue about three weeks, generally take place in the course of October. More intent upon the quantity than the quality, the proprietor bestows little care upon gathering only the ripe and sound grapes. The vintage is seldom interrupted, or suspended, to wait for the perfect maturity of the fruit; in from fifteen to twenty days the whole is finished in the vale of Marcillac, and the vintage scarcely lasts four or five days in the same vineyard. It is not thus that the work is performed in the vine lands which furnish the good qualities of Bourdeaux wine: there they pick constantly, and the vintage continues for one or two months. No great advantages, it is true, would be obtained at first by similar care in the vale of Marcillac, but in the end it would be found not wholly useless, for complete ripeness was never yet a defect.

The vintager receives for hire 20 centimes a day, and his food, representing a value of 50 centimes.

The grapes are carried from the vineyard to the vat in double panniers, which are placed upon cushions of goat skin, of a triangular form, with the angles rounded. Seen underneath, these cushions represent, towards the sharpest of their angles, a cap or hood to receive the top of the head, and towards the opposite side two small cushions near together, designed to protect the shoulders on which the two divisions of the pannier rest. The head of the porter being placed between these divisions, the pannier is prevented from slipping back by a band of osier attached to its two divisions, and against which the anterior angle of the cushion presses. This pannier, which together with the cushion, weighs five or six kilogrammes, contains from 40 to 45 kilogrammes of grapes.

It is wonderful to see the porters, under this heavy burden, descend at a rapid pace, with the aid of a long staff, from the top to the bottom of the vineyards or climb up them by goat paths, and often traverse more than half a league without relaxing their speed.

If we judge of them by their gait when they return unloaded, to the vineyard, they do not then feel so much the necessity of hurrying themselves.

Their stature generally corresponds with the muscular force required by their employment, which is at once laborious and dangerous.

The number of porters is determined by the abundance of the crop and the distance of the vineyard from the cellar. When this distance is great, oxen are used to haul the grapes which, in this case, are put into a large tub placed upon a cart. The porters then, have only to carry the grapes from the vineyard to this tub which is generally not far distant; their task, however, is not therefore lessened, for they are fewer and more frequently obliged to go up and down the steep paths of the vineyard, the most dangerous and most difficult part of their work. Their wages and food agree with their service; they receive, per day, from one franc twenty-five centimes to one franc fifty centimes, and they make eight or nine meals, which, together, are worth two francs at least. We are, at first, no less astonished at their digestive capacity than at their muscular powers; but the one is soon explained by the other.

When the grapes reach the cellar they are poured, generally without being stripped from the clusters, upon a table pierced with holes, surrounded by high raised sides and furnished with a trap-door. This sort of chest is fixed upon handles, by the help of which it is carried like a hand-barrow, and placed horizontally on the vat; it is called *gabio*, which signifies a cage.

A man, who receives the name of *gabrazre*, because he works in the *gabio*, enters it with naked feet and legs, and tramples the grapes. When the operation is ended, he opens the trap-door and throws into the vat whatever has not already fallen through the holes of the cage.

This trampling is not practised by all the owners of vineyards; there are some who pour the grapes at once into the vat, where they are afterwards crushed as well as their situation will permit.

Some proprietors strip a portion of their grapes from the clusters. My honorable friend, M. de Cabnères performs this operation upon all his. He has a double bottom fixed above the grapes which keeps the *œne* beneath the surface of the liquid; and a cover or lid placed and luted upon the vat prevents all evaporation. The results obtained by this intelligent proprietor establish beyond a doubt, that the wines of Marcillac might take their place among the good wines of France, if in the vine lands of this name the culture of the vine and the making of the wine were directed by men like him.

The question, however, whether it is proper to strip or not to strip the grapes from their clusters cannot be determined by the success of a single individual in a tract composed of such a variety of grapes, soils, and exposures. The introduction of the clusters whole, facilitates fermentation, and, by the principles which it furnishes to the wine, gives it sprightliness, renders it piquant and lessens its tendency to become thick or oily, *(tourner au gras.)* In these respects it becomes useful, when without it the wine would be very weak and tasteless, and could not be preserved without difficulty; and consequently it is proper on the hills where a sweetish taste predominates, and from which only a wine of very weak quality can be expected. But it is not the same with the crops in which *aroma* and sugar abound, at least sufficiently to enable us to calculate upon a generous wine, agreeable to drink, and easy to be kept by the ordinary processes of racking, [*mutage*] and fining. In such situations it is proper to get rid of the astringent principle. It may then be of advantage in one place to strip all the grapes from the clusters, in another to strip only a part of them, and in a third not to strip any; and each person ought, in this particular, to pursue the lessons of experience, taking care to modify his practice when the circumstances under which it was established are no longer the same. It might have been proper formerly to strip off the grapes of a particular vineyard when it was planted in *menu* and received but little manure, while this would no longer suit since it is planted in *moissagues*, in *maural*, in *canut*, or other varieties which produce only flat wines and since it receives much manure.

The fermentation generally goes on in an open vessel, whence it follows, first, that the *must* does not contribute at all, or it contributes very little by its own oxygen, to the formation of the carbonic acid gas, and that a less quantity of this gas is absorbed by the wine: secondly, that the *must* loses more of its carbon; that its hydrogen and oxygen may be united in greater quantity to form water; that alcohol is produced in less abundance; that the evaporation of this as well as of water is greater, that, in fine, there is less wine, and that this wine is of weaker quality.

The grapes generally remain ten days in the vat: the duration of this stay is abridged or prolonged according as the weather is warm or cold, and the ripeness of the grapes more or less complete. When, from the abundance of the crops and the want of vats, it has been necessary to remove the wine before its fermentation was entirely over, the result has been a better wine, but more disposed to become thick, doubtless because there remained in it a greater amount of carbon united with its mucilage. Here perhaps the unsuitableness of habit is felt in a change; because it was right to keep the wine ten days in the vat, when the *menu* containing a great deal of sugar predominated in the vineyards, it is thought proper still to give the same time when other varieties which produce grapes less sweet and weak wines have been substituted for the *menu*.

Some wine-makers, however, take their wine from the vat before the tumultuous fermentation is entirely over, and they applaud the practice; as their proceeding is rational I can easily credit their success.

The fermentation is often facilitated by pouring into the vat a certain quantity of *must* boiling hot; but this good method is proscribed by the prejudices of certain makers who consider wine thus made as adulterated.

During the fermentation a naked man enters once a day into the vat, and returns towards the bottom the stems and woody fibres of the clusters *(rafle)* which the fermentation has raised to the surface: he crushes, besides, the grapes when they have not been trampled in the *cage*. This operation becomes dangerous if the vat is only half full. The danger and the accidents are increased by the intoxication of the persons who are exposed to them: in 1831, an imprudent vine-dresser perished in a vat, in a state of asphyxia.

The temperature in the vat rises in the course of the fermentation to 25° or 26°, (centigrade,) that of the store-house being 15° or 16°.

When the fermentation is over, the wine is drawn off through a hole, made for that purpose at the bottom of the vat, and kept free from the obstruction of the *marc* by tiles, vine-branches, or other articles. On some estates the cellar is under the store-house, and the wine flows of itself, conducted by tubes, into the casks which have been cleansed and prepared beforehand for its reception.

When the wine has ceased to flow and no more remains in the vat the *marc* is taken out and subjected to the action of the press, an enormous square beam of oak fixed as a lever of the second order, on which the power is applied by means of a screw, of which it becomes the nut, and which three men turn by the help of three other levers: this screw tends to press together the thick and heavy plank of the table on which the *marc* is placed.

This wine is put away separately, or mixed with the first to give it a deeper color.

Wishing to have the means of increasing this depth of color, some proprietors cultivate the variety called *teinturier* the whole merit of which is to produce a wine as black as ink.

The great value attached to the coloring of the wine proceeds doubtless from the preference given by *the trade* to that which is highest colored, and this preference is itself founded in part perhaps on the capability of the high colored wines to receive, without its appearing, at least, to the eye, a certain quantity of water.

Yet, is it really indifferent whether the wine contain much of the coloring principle or be almost deprived of it? On this question it may be observed, that wine as it acquires age, loses its color and improves in quality, and besides, that many poor wines are very high colored, but that would not prove that it is useless to wine to have color at first: to determine this question it is proper to collect all the facts, reserving the endeavor to ascertain the cause of them afterwards. Wines deprived of this principle, when first made, easily become thick or acid, and the more certainly the more completely they are deprived of it. When wine becomes thick it loses its alcohol and acquires oil: it becomes acid only by contact with the air. It ceases to be liable to turn acid when it is deprived of that mucilage, which some chemists have called *extractive*, considering it as a distinct substance: by this mucilage also wine is capable of becoming thick; the most mucilaginous wines are the most subject to this fault.

The more coloring principle there is in the grapes, the more tartar also is there in the wine. The mucilage, the tartar, and the coloring principle are precipitated together, and form the lees. The mucilage is not precipitated in white wines, at least it is not precipitated either so promptly or so abundantly as in red wines; yet in the first as well as in the last, the tartar is precipitated, whence it may be concluded that the mucilage is precipitated by the coloring principle. In separating from the lees, the wine does not lose its alcohol, and becomes less and less capable of turning thick or acid.

These facts prove that the coloring principle is useful to the preservation of the wine so long as the mucilage is not precipitated; they enable us, besides, if I am not mistaken, to understand more easily, some phenomena which are displayed in the wine, which depend in some measure upon this principle, and which explain, at least, in what manner the color may contribute to the preservation of the wine.

When, in the spring, the mucilage undergoes a new fermentation, the carbonated hydrogen which is disengaged decomposes a part of the alcohol, and is combined with its constituents in the proportions requisite to make oil; the whole quantity of alcohol is diminished, the mucilage puts on an oily appearance, and the wine has become thick. The coloring principle, which is itself without action on the alcohol, becomes nevertheless an obstacle to its decomposition, by fixing, in the mucilage, to which it is capable of being united, and which can even dissolve it, the tartar which accompanies it, and which tending, as well as sugar, to form alcohol, ought to prevent its decomposition. By being precipitated to the bottom of the casks, carried down by the coloring principle and the tartar, the mucilage ceases to be in contact with the air: it has scarcely any fermentation, and the acidification of the wine is more difficult. I submit to the judgement of chemists this theory, incomplete without doubt, false perhaps, and which I offer only with very great and very well founded diffidence.

When no more wine can be produced by the action of the press, a colored liquid is obtained by watering the *marc* and pressing it again: this makes the *piquette* which is the ordinary drink of the wine-dressers when they are not supplied by the proprietor.

Every year at the commencement of the spring, prudent proprietors rack their wine after having fumigated the casks destined to receive it by burning a match made of cloth dipped in sulphur, four *centimetres* wide by two in length, for each *pipe* in quantity. The cask in which the match has been burned is left shut close for five days; sometimes aromatic substances are added to the sulphur which forms the match, whence results a perfumed flavor, an artificial *bouquet* which is not equally agreeable to all amateurs. Fining the wine with the whites of eggs is practised by only a small number of economical and careful proprietors.

The wine of Marcillac, it is said, cannot bear transportation and keep long; this is a mistake. I have drank it at Paris very good, and four or five years old, coming from the hill of *Gradels*. The wine of the hill of *Cruou*, when made with selection and care, can keep for twenty years, the ordinary term of the ancient Falernian. On this same hill a wine is obtained worth from two to three hundred francs the hectolitre. But an old custom decides peremptorily one of these questions. In the years when the best wine was made, the inhabitants of the place who were in the most easy circumstances, formerly filled a cask with it, from which, after four or five years, they drew successively what they required for their consumption, and replaced it afterwards with new wine: this cask became thus inexhaustible, and was called the *tonneau perpétuel*. Would this custom have existed if the wine would not keep?

If however the wine of Marcillac has lost in general, something of its old quality, it is, doubtless, because the cultivators have given up, as not sufficiently productive, the plants with grapes containing much saccharine matter, but small and few, to substitute for them vines with grapes less sweet, but large and numerous; and besides because they neglect the means to prevent the wine from becoming thick or acid, such as racking, [*mutage*,] fining, and when necessary the addition of a little sugar or boiled *must*, when the weather has been rainy before or during the vintage, and when the wine is weak.

From the various qualities of its soil, and the different temperatures of its climate, from the activity of its inhabitants, from its proximity to lands cultivated in grain, and the facility of obtaining from them the dung of sheep, preferable in all respects, to the manure from half rotted dunghills, mouldy and sometimes of an infectious smell, the canton of Marcillac is capable of producing various qualities of very good wine, the best of which would yield in nothing to the finest wines of France. That the art of wine-making may reach this high degree of perfection, only three things are required, instruction, inclination and capital. Are we advancing towards a future which permits us to hope that they will at last be found united? I dare not on this question affirm any thing, except that this future will be realized only inasmuch as there shall be great profits in attending to the quality, and as this attention shall be excited by powerful examples; or in other words, it will not be realized till the contrary of what now exists shall happen.

Among the obstacles to perfection in wine-making may be reckoned, the temperature of the cellars, most of which, like the vineyards, have a southern aspect; the retail trade, which leaves the wine of the casks which have been broached, exposed for a long time to the contact of the air; the terrible prejudice that all wine managed by a new process is an adulterated wine, which will produce deleterious effects on health, and which should consequently be distrusted, however agreeable may be its taste; the substitutions by which the carriers, to the prejudice of the quality, know how to render their unfaithfulness undiscoverable by measure; a fraud of old date which became in 1550 the object of a severe sentence by which it has not been abolished.

The wine of Marcillac, the trade in which scarcely extends beyond the limits of the department of Aveyron, will soon be indebted for a great market to the immense and magnificent establishment of Decaze-Ville, situated in a canton contiguous to that of Marcillac, and near which will be soon collected a people of smiths: to these, often thirsty, this wine will appear much more agreeable and more wholesome than the fiery wines of Languedoc. It is thus that great enterprises give life to the countries that become the theatres of them: honor to those who undertake them with all the means which presage their success.

FOUR-FIELD FALLOW SYSTEM, AS OPPOSED TO THE THREE-FIELD ROTATION,

Being a Cursory Review of an article No. 9, Far. Reg. (Vol. I.,) under the signature of Wm. H. Roy, Esq. in support of the latter.

To the Editor of the Farmers' Register.

> I sing the tillage old Virginia knows,
> Which cheats with hope the husbandman who sows;

> *Old Virginia Georgics.*

In reviewing the causes which have operated to retard the agricultural advancement of Lower Virginia, it has long been the settled conviction of my own mind, that the most extensive and fatal, if not that of paramount importance to all others, was to be found in the *odious* three-field system. It is still a question of doubtful solution, to which of the two principles mankind have alternately yielded the most absolute dominion; that of the sanctity of time, and custom, on the one hand—or, of an inordinate spirit of innovation on the other. While the latter is decidedly the master spirit of the age, and has extended its influence to all other classes of the community—even that of the agricultural—the former still retains and exercises its ancient and uncontrolled supremacy. In no department of the arts, or indeed of the sciences, (for to that distinction may agriculture now confidently aspire,) have greater improvements been effected than in the theory, philosophy, and practice of farming. Chemistry has shed a flood of light over the whole subject, illustrating its principles, and establishing its laws, on the sure basis of scientific truths—improvements of acknowledged practical utility are daily made; errors both in principle and practice exposed. But yet by the great mass of our community, they are received with distrust, denounced as innovations, or passed unheeded, as the illusions of the theorist; and they still plod on in the "good old way" to ruin—with the same pertinaceous adherence, and no better reasons, than did the old Dutch settlers of Kinderhook, because forsooth, their fathers had done so before them. To the influence of this principle are we indebted for that system, the defects of which, it is my present purpose to expose. Looking as I have done to the explosion of this, and the adoption of some better system, as the only hope for any extensive, or permanent improvement in our agricultural condition, I had early designed making it the subject of a communication, if for no other purpose than that of inviting others more competent than myself to the task.

In this design however, I happily found myself anticipated, and after the two able, and. to my mind, conclusive articles of Messrs. Selden and Carter, considered the whole ground as completely occupied, and that more, neither could or need be said. Presenting as they did, a plain and unquestionable record of practical results, read, discussed, and admitted, as they generally were, I had anticipated from them, the most happy effects—all things, in fact, seemed to afford the most favorable auguries. Through the joint influence of your Essay and your Register, a spirit of inquiry had been aroused—better hopes had been inspired—the *vis inertiæ*, so long felt, removed, and a new impulse every where given to the work of improvement. In the transforming effects of calcareous manure, an approximation seemed really made to the long sought principles of the alchemist, and in the fond hopes of the farmer, were again amusingly revived the bright visions, and early dreams of that visionary—a new era had indeed arisen—the revolution so important to be effected, seemed at least in progress of successful accomplishment, and the future in bright perspective, broke forth in all the beauty of renovated nature: our worn out fields, and poverty stricken herds, (the too faithful moral portraiture of our condition) had assumed a new aspect, and already teemed with life, luxuriance and comfort. But, alas! this was but the day-dream of a too sanguine imagination! A sad reality, in bitter mockery, every where meets the eye.

Among the advocates of the three-field rotation, I regret to find my friend and neighbor, Wm. H. Roy, Esq., a gentleman whose sound and practical views, on all subjects, and whose success as a farmer, justly entitle his opinions to much weight and deference. I cannot better effect the object of this communication, than by glancing at a few of the arguments urged by him, in the article above referred to.

The first position assumed is, "that ours is not a wheat growing country;" and the inference thence deduced, that Indian corn should be our primary crop. When the major proposition is established, I will admit the minor. But by what process of reasoning does he arrive at this conclusion? By "observation, and the experience of years, which have convinced him, that the wheat crop is precarious, and subject to numerous casualties, which no skill or industry can remedy." Let us not, however, take the fact, without investigating the cause. He proceeds, "it not unfrequently happens in the spring, when the wheat is in bloom and promises an abundant yield, that the hopes of the farmer are blasted by an easterly storm. Indian corn is the only crop on which he can with safety rely." Would it be right then, he asks, "to adopt a system which would render wheat our primary crop?" Would it be right, (if I may be permitted to answer this question by asking another,) to persist in a system, which year after year, but mocks us with disappointment? I do not maintain that ours is a wheat growing country—nor, consequently, that wheat should be made our primary crop. But I do maintain, that the converse has not been established—that our entire system is opposed to its success—that its cultivation should either be abandoned, or that, to the extent cultivated, recourse should be had to some more ameliorating system, and that the very admission of the fact of "uncertainty," is the strongest possible argument in support of this. Nor is the conclusion drawn from our want of success, a legitimate one. By parity of reasoning it might be shown, that James River, and other sections of country, (for there this system has been repeatedly tried, and with no better success,) were not wheat growing regions. Can it then be expected, that a system which has entirely failed in a location naturally adapted, both by soil and climate, to the production of wheat, should not fail in one acknowledged to be defective in both? And does not the fact of its "being uncertain and subject to numerous casualties," give it an additional claim to the fostering care of the most judicious and approved cultivation? But it is "by the easterly storms that the hopes of our farmers are so frequently blasted." Here we join issue—now I do not imagine, that clover fallow is to afford an effectual protection against this evil; but I do suppose, that it would go very far in counteracting its effects. I take it for granted, that whatever contributes most to the health and strength of a plant, contributes at the same time most to the probabilities of its success. No one I suppose would hesitate to admit, that a healthy and vigorous crop is, in the first place, much less liable to disease of any kind, than a feeble half starved one; and that if attacked, it would successfully resist disasters, to which the latter would fall a ready victim. As well might we compare the ability of the nursed up invalid to resist the winter's blast, with that of the hardy nursling of the storm.

"I will concede," says the writer, "that land will improve faster under the four-field system, &c." An important concession, truly—involving, I conceive, the whole matter in controversy. Land constitutes the principal capital, and its improvement I had supposed the principal object of every farmer. To this end are all our efforts directed, and by its subserviency to this purpose, do we pronounce upon the value of every system. Of what importance are a few abundant crops, provided they leave us in return, an impoverished and worn out soil? Let us but make our land rich—adopt that system as the best which most readily effects it, and we may then cultivate as either taste, interest, or pleasure dictates.

"Indian corn," again proceeds our author, "is the only crop on which we can with safety rely. In a country not well adapted to hay, it furnishes us with the means of supporting stock, and of manuring extensively." I admit the justice of the eulogium, and have certainly no disposition to quarrel with our best friend. With us it does indeed constitute the staff of life. It is with the system alone that I am at war; and to that I cannot concede the superiority claimed. That loss in the corn crop will be sustained for a year or two, is probable; but that as soon as in full operation, and the effects of the system are fully felt, that that loss will be more than compensated, and that one-fourth of the same farm, will produce as much as one-third had previously done, there can be but little question. Upon this hypothesis, (and it is one which may be sustained by a reference to the actual results of farms under the two different systems,) no diminution of the corn crop being sustained, it follows of course, that there can be no diminution of material, either for manure, or the support of stock. On the contrary, from the increase, (say the three-fold production of the wheat crop) the material for both purposes is greatly augmented, in the articles of wheat straw, clover hay, pasturage, &c.; and these, together with the increase of product, may be struck, as a fair balance, in favor of the fallow system. It is thus under this system that wheat becomes the primary crop, not by any actual diminution of the corn crop, but by the increased production of the former; and surely to its priority on such terms, none of us can object.

"But," says the writer under consideration, "after all, facts afford the best arguments." "I have noticed with minuteness and attention, the experiments of several of my neighbors, and will give you the results. One divided his farm into four-fields, and cultivated them successively in corn. His land, judging from the growth of vegetable matter, evidently improved—yet, his corn crops declined, and his wheat crops were generally destroyed by insects. He was compelled to return to the three-field system." The instance here referred to, affords a fair specimen, and the results a fair commentary on the four-field system, as pursued among us. I beg leave to state, that it was not the four-field fallow system now in vogue, as known and practised on James River and elsewhere, but that introduced by the late Col. John

Taylor, of Caroline—in other words, a turning out for four years in succession, with a certain prospect at that time, of an abundant crop of pine bushes, broom straw, and of every noxious weed, with which the iniquities of our first parents were visited. "Another gentleman, possessing more enterprise than his neighbors generally, divided his farm into five-fields. His crops of corn and small grain, have retrograded. He has had several crops of wheat on his fallow fields, which promised a most abundant harvest; and yet from insects, or storms, or some other casualties, he has always been disappointed in his expected harvest. This last gentleman possesses all the requisite skill and and industry to insure success. He will, I doubt not, although he is unwilling to admit it, yet return to the despised three-field system." Really I had expected more magnanimity! Such enterprise, skill, and industry, deserved a better fate! But, alas! who can contend against fortune —against the combined powers of insects, storms, and other casualities? He has, in truth, returned to that despised system. "Another neighbor has been cultivating his farm in four-fields for several years. His small grain crops increased; but latterly a great change has taken place—his barley crop (his principal reliance) has gradually dwindled away; until this year, he may be said to have sowed himself out of seed—and fairly abandoned the crop." The gentleman here alluded to, deserves to be particularly mentioned, as the first who had the boldness to set up for himself, and introduce the new system among us. His success for several years was signal—so much so, as to attract the attention of all, and to induce a few others, partially and cautiously, to follow his example. The production of his farm under this system, I have no hesitation in saying, has been double that under the former system, and greater by far than that of any other farm of the same size and equal fertility. I allude to the grain crop; nor am I aware, nor do I believe, that any diminution has been sustained in the corn crop. A series of disasters, it is true, he has shared in common with others—Mr. R., himself, not excepted—but under all circumstances, his crops have been better than any in the neighborhood.* "I will cite you another case—a farmer very near me, a particular friend, &c., divided his farm into four fields. He has made great exertions to improve it by manure, rest, &c., and his success is very flattering, &c.—yet, I think, he is nearly convinced that the four-field fallow system will not answer, and that he will speedily abandon it. His small grain crops have never come up to their promise, and the wild onion is gaining rapidly on him."

For that gentleman, I take it upon myself to say, that although his crops have not been adequate to his expectations, yet, that his confidence is undiminished, and his perseverance unsubdued. To the onion he pleads guilty. True it is, that at various times, in consequence of not grazing, it has taken almost entire possession; but yet, after a doubtful and protracted conflict, his crops, both of wheat and barley, (through the redeeming virtue of fallow) have invariably obtained the mastery. The wild onion, I will here take occasion to add, has almost entirely given way; and to perseverance in the system, he confidently looks for its entire eradication. I will add, that while clover constitutes the chief excellency, and an indispensable part of the fallow system, yet, that in none of the instances above referred to, was recourse had to it, and that success ought rather to have been a matter of surprise, than of reasonable expectation.

In concluding this hasty review, I cannot but advert to the silence, and becoming modesty, with which he passes by the success of his own experiments. I submit it to his own candor to say, if in the several instances in which he has tried fallow, he has not more than doubled, if not trebled, the production of the same land, wheat succeeding corn. In the last instance, on a lot of several acres, a crop of 25 bushels per acre was produced. Now, if one or more acres, under a certain system, be capable of producing a certain crop—why may not a greater number under the same system, and similar circumstances, produce a similar crop? On the ordinary principles of induction, may I not then conclude, that the same system *in extenso* would be attended with the same results; and (reasoning *a priori*) derive an additional argument in support of the position assumed —that want of success is not so much attributable to soil, or climate, as defect of system.

I cannot in stronger terms express my unqualified condemnation of the three-shift rotation, than by adopting the words of that distinguished agriculturalist, Col. Taylor of Caroline. "As a system," says he, "for extorting crops from the earth, it is precisely similar to the rack for extorting truth from the sufferer. It stretches, tortures, mangles, obtains but little of its object, and half, or quite kills its victim. This three-shift system has only one merit—honesty. In theory, it promises to kill our land; in practice, it fulfils its promise." With him I cannot accord to it, even the merit of honesty. It professes, in fact, to improve, and under the imposing guise of friendship, inflicts the deadly wound.

A chief objection to the system, consists in its hostility to the cultivation of grass; and a capital defect growing out of it, among our farmers, is that of an entire reliance on artificial putrescent manure, to the neglect of the more important auxiliaries, of green succulent vegetable crops. Among these, red clover claims a decided pre-eminence. Yet, strange to tell, while in other sections it has been regarded as the most important, if not the only real efficient agent; with us it has been entirely neglected; at least with reference to the improvement of land. I know of nothing which would be regarded with more incredulity, than the assertion that a good crop of clover was equal to a plentiful dressing of stable manure—yet we have the authority of Messrs. Carter, Selden and others, for the fact.

An unfortunate impression prevails, that our lands are not adapted to clover. I do not assert that they possess that peculiar aptitude for it, which characterizes the James River and mountain country; but that it can be cultivated to great advantage even on our worst soils, improved to a

*This statement, however contradictory, is not designed to impugn the correctness of that of my friend R. It is given as a mere matter of opinion, on a subject of fair difference, and in the absence of any certain data.

certain degree, (and with us such improvement is always pre-supposed) admits of but little question.

The greatest obstacle with which we have to contend, arises, I have long thought, from the fact, that from the neglect of the cultivated grasses, our lands have become so completely pre-occupied by noxious weeds and other grasses, as to afford in the contest for possession, a very undue advantage to these, the primitive and rightful tenants.

The efficacy of plaster, in consequence of our contiguity to the sea, and the supposed neutralizing effects of saline atmosphere, has also been much questioned. So far as experiments have been made, their results have been so equivocal and unsatisfactory, as to leave the subject still entirely problematical. The use and value of ashes, calcareous manure, &c., in counteracting this effect, (as suggested by yourself and others,) is a subject of interesting inquiry, well worthy the attention both of the practical and scientific agriculturalist.

But, say the advocates of the opposite system, what obstacle is there to the cultivation of clover under the three-field rotation, with the addition of a standing pasture? To this I will simply object, that it is a begging of the question—that it constitutes no part of the system—that clover is principally valuable as a fallow crop for wheat—that corn requires a clean preparation, and (as generally admitted,) seldom succeeds on a clover lay. It is in the application of manure, that the beauty of the system is particularly seen. Manure is to the farmer, what principal is to the money lender. The value of both depend upon the activity with which it is employed, and the return annually made. If it is a sound principle with the one, to collect punctually every year his interest and add it to his principal, it must be a bad one for the other to await a precarious return but once in three years. There is nothing so discouraging to a farmer, as to find at the expiration of that time, all his labor lost, (as is the case in most of our soils,) and nothing but an increased necessity for renewed exertion. If his manure is to be evaporated and lost, why not derive the benefit of it to a crop. Here the clover crop interposes its kind offices. By this it is taken up, secured from loss, held in trust for the benefit of the land, and in the admirable economy of nature, returned in a new and modified form to the purposes of its own support.

The value of clover admitted, and the practicability of its cultivation established, the superiority of the four-field fallow system must be conceded—three-fourths of your land being in active production, and the remaining portion under a course of regular and progressive improvement. The limits assigned to an article like this, (and which I have already greatly transcended,) forbid me farther to enlarge on the many other advantages which might here be mentioned. Facts, however, "after all afford the strongest arguments." Compare then those sections in which the two systems have been respectively pursued—point out the individual instances of success under each—show me the estate under the three-field system, which, either in its profits, or the rapidity of its improvement, can compare with that of Woodstock, Westover, Shirly—raised as if by the magic of a system, from the ruin and desolation to which they were reduced, by the scourging effects of an opposite course. We have among us intelligence, energy, and enterprise—no where are the evidences of these more obvious—neatness, order, good cultivation, and general good management are striking features—and challenge from every observer a proud contrast, with that of most other sections of country. But yet our lands, with few exceptions, are scarcely stationary—our citizens, worn down with toil, and disappointed in their expectations, are seeking in the "far west," the land of hope and promise, and leaving to ruin and abandonment, the neglected fields and deserted homes of their fathers. Let others seek in the romance of their feelings, the wildness, vigor, and untamed luxuriance of the west. Give me, (and would that I could inspire others with the same hallowed feeling,) give me, the endearments of early life, the social enjoyments, and solid comforts of the old states, pressing rapidly onward as they are, in their career of improvement, and destined as they soon must be, to rival even the old world, in all the improvements and refined elegancies of life.

W. T. T.

Gloucester County, April, 1835.

FREDERICK AND JEFFERSON COUNTIES—REMARKS ON THE CHARACTER OF THE COUNTRY, AND THE SYSTEM OF CULTIVATION.

To the Editor of the Farmers' Register.

Most of the readers of the Farmers' Register have heard much, and few comparatively have seen any thing of the Valley of Virginia, that par of it especially which borders upon the Shenandoah and the Potomac rivers. Some remarks upon the character of the country, the system of cultivation, &c. may not be unacceptable to the public. No part of Virginia has been improved to so great an extent, and with so great rapidity, as the region of country which I have mentioned.

The best portion of the county of Frederick lies to the east of the Opequon and borders upon the Shenandoah river; it joins the beautiful county of Jefferson, which through its whole extent, has the same river as its eastern border, and the Potomac river as its northern limit. The same vein of land runs through the upper and better portion of the state of Maryland, and through Pennsylvania to Philadelphia, embracing in its course, the justly celebrated counties of Cumberland, Lancaster, York, and many others. My remarks are intended to apply to the part of the county of Frederick above mentioned, and to the county of Jefferson, because with them I am familiar. The extraordinary point of improvement, fertility, and value to which the Pennsylvania portion of the valley has attained, has been produced by the absence of slavery, and the consequent division and subdivision of the land into farms of from ten to one hundred acres. Of course we can enter neither into comparison nor competition with them in the absence of the cause of improvement to which I have referred. I believe however, that the portion of Virginia alluded to, is in no respect inferior, in natural fertility, to any part of Pennsylvania.

Our lands are very much broken with ledges of limestone rock, causing great labor and expense in their cultivation—though this inconvenience is very unequally felt in different places, diminishing generally as we approach the rivers. The country is for the most part abundantly supplied with limestone streams—though we have reason to fear that this great advantage is lessening every year from summer droughts. Certain it is that both the springs and streams flowing from them are much less copious than they have been within the recollection of many living witnesses. In fact, the great enemy with which we have to contend is drought. Our lands burn easily from the great quantity of limestone at and near the surface, and hence our cropping is precarious, except upon well improved lands. With all of these disadvantages, (and I may add to them a harsh and most capricious climate) agriculture is in a prosperous condition, and the price of lands immensely high. It will be recollected that about the year 1817 lands had attained a price totally disproportioned to their productive value—from sixty to eighty dollars per acre being the current rate. The reaction, which afterwards followed, reduced them as much below as they had been above their real value. One of the best farms in Jefferson county sold under my own observation, for twenty dollars per acre. It has now settled down at a mean between the two extremes, and the present value of good land may be fairly stated at from thirty to forty dollars.

Clover and plaster of Paris are here, as elsewhere, the instruments of improvement. Soon after the introduction of plaster among us, our most energetic farmers used it with great effect; and judging that the benefit would be proportioned to the quantity used, it was laid on with a lavish hand. Hence it resulted that the land became, as it was termed, "plaster sick," and no continuing benefit seeming to follow, it was in a great measure abandoned. The circumstance was eagerly seized upon by those averse to the expenditure of money upon their lands, to justify their neglect of its use altogether. As soon however, as the effects of its former use had worn off from the lands which had been benefited by it, it was discovered that the clover ceased to grow luxuriantly, and of consequence that there was an end of improvement, most sensibly felt in diminished productiveness. It was therefore again brought into free use, and is now in as high favor as ever, with a much better understanding of its properties. No farmer now thinks of using clover without plaster, it being a concession, that it is entirely dependent upon this valuable auxiliary for its efficacy.

Manuring is also extended as far as practicable by every one—though the manner of applying it is various. Many persons feed their stock through the winter upon the hills and galled spots in the open fields. Others pen them near the straw-ricks, and leave the manure to be afterwards hauled upon the field where it may be wanted; while others (more particularly small farmers) adopt the old system of bringing every thing to the barnyard. No attention is paid to mixing manures for compost: that which is in order is usually put upon the corn land in the spring, while the rough or only partly rotted is reserved for fallow in the autumn. The old practice of ploughing in the manure generally prevails, though many of us have been induced by what we have read in the Farmers' Register, and elsewhere, to try the top-dressing, and I think the latter plan is growing into favor. While I do not question its adaptation to the porous and sandy soils of the lower country, I have apprehended great loss from evaporation in our stiff, unyielding lands. It is a question of great importance, and it is hoped that continued discussion and experiment may lead to some satisfactory solution.

Our staples are, as you know, wheat and corn; rye and oats are made for home consumption. The market for corn has been confined to the neighborhood sales, from its not bearing the cost of distant transportation. Indeed, no effort is made to produce it beyond the point of home consumption, and the necessity of freeing the land from blue-grass. Wheat is our only article of export, and every thing is made to yield to its culture.

Here, as in almost every other part of Virginia, the land has been reduced by close grazing. We are, however, fast awaking to the impolicy of this course. Even those who have been in the habit of purchasing cattle for future sale, (the only profitable grazing,) are giving it up. We have no standing pastures, being dependent upon the cropping fields for pasture. Add to this, we have discovered at last, that our corn-stalks and straw will yield more manure when wastefully given to a few cattle, than when altogether consumed by many.

I do not think that a particular rotation of crops is much observed among us. We cultivate in corn those fields which are too grassy to promise a crop of wheat without cleaning, and generally fallow in alternate years those which will answer for wheat, as long as their condition will permit. I will here remark, that we understand the term "fallow" to mean exclusively those lands which have laid out of cultivation for a year or more, whether naked or in clover, and which are broken up for wheat in the summer and autumn. I think the term has been frequently used by your correspondents in a different sense. Corn field wheat, except when highly manured, very rarely yields a tolerable crop. Hence, a practice is fast obtaining—more especially in Jefferson—of leaving the corn land over for fallow the succeeding year. However adverse to sound theory it may seem, to leave land thus naked, certain it is, that in practice it answers remarkably well; and I believe that it will be within a few years very commonly adopted. I understand that this practice is very general in Frederick and Washington counties, in Maryland, where the lands are admirably farmed. Our proper rotation will then be as follows: 1st. Corn. 2d. Rest. 3d. Wheat; followed by clover. 4th. Rest in clover. 5th. Wheat—growing a crop of corn and two of wheat fallow within five years. When a good crop of clover has been turned under for wheat, many of our best farmers venture to stubble for a second crop.

An interesting experiment has been tried upon corn land; just after the last ploughing, clover-seed has been sowed, and the result would have been highly satisfactory but for the summer drought, which we rarely escape.

Corn land is also very often left over for oats and clover in the spring, and has always produced better than other oat land. The clover sown upon the fresh land immediately after the oats are harrowed in, will very generally succeed much better than when put in the usual way upon the wheat lands.

The heavy expense attending the carriage of our products to market has been heretofore a great drawback upon the prosperity of the valley, and nothing except flour has been available at all. A better day has now dawned upon us. The Chesapeake and Ohio Canal, and the Baltimore and Ohio Rail Road, both now in full and successful operation to Harper's Ferry, give us an outlet at that point, and have already reduced the expense in a very great degree. Within another year the completion of the Winchester and Potomac Rail Road to a junction with those great works, will leave us nothing to desire as to transportation, and must very materially enhance the value of our lands.

Our prospects for the present year have been marred by the unusual severity of the past winter. The cold and dry autumn prevented the vegetation of the wheat in due time. It came up under the snow in January, and began to promise fairly, but the subsequent intensity of the cold appears to have destroyed it in its tender state; and now it is very certain that the crop will be a very short one.

The foregoing remarks are designed to describe things as they are in this part of Virginia, and although devoid of any particular novelty, may not be without interest to those who desire information.

A FREDERICK FARMER.

From Dr. Lardner's Second Lecture on Steam, Delivered before the Liverpool Mechanics' Institution.

NEW MOVING POWERS, AND IMPROVEMENTS ON THE USE OF STEAM.

The celebrated Leslie has invented a method of producing ice, by the employment of sulphuric acid. This acid has such a strong affinity for water, that if it is present in an atmosphere filled with vapor, it will immediately seize upon the vapor and incorporate it with itself. He places water in a watch-glass under an air-pump, with sulphuric acid near it: the air being withdrawn from the pump, the sulphuric acid seizes upon the vapor as it rises from the water, and the water parting with all its heat to maintain the vapor, is converted into ice. In performing this experiment, it is necessary that the vessel containing the sulphuric acid should not be in contact with the water, otherwise the degree of heat which accompanies the combination of the vapor and the sulphuric acid would prevent congelation taking place.

A very pretty experiment, to prove that the atmospheric pressure is a great agent in preventing water from boiling, can be performed with a flask half filled with boiling water, and closed at the neck. If it is in that state plunged into cold water, it will boil; but the ebullition will cease when plunged into boiling water. This is because the cold water condenses the steam in the upper part of the flask, and, by removing the pressure, allows the water to boil; whilst the hot water keeps up the temperature of the steam which presses on the surface of the water so as to prevent it boiling.

From these investigations it may be concluded, that a liquid or gaseous state is not essential to the nature of any substance, but that its state is entirely dependent on the supply of heat which that substance has access to. We know that water can be passed through these three states, by the abstraction or the application of heat. Fluid mercury may be evaporated, and the fact ascertained by passing the vapor through a cold tube, and it will again assume a liquid state; it may also be made solid, so as to take a shape like a metal. The most refractory substances we know of are capable of being converted into liquids by heat. All the metals we know of may be brought into a state of fusion by a proper supply of heat; indeed, all substances, by proper treatment, may be seen in the solid, fluid, and aeriform state. By turning the rays of the sun, through a lens, upon gold and pantinum, we can decompose them, and convert them into gas. There is only one solid which has not yielded to fusion, and that is carbon, or the diamond; but we can only conceive that we cannot reduce it, because we cannot command a sufficient quantity of heat to melt it and maintain it in a liquid state. Of all liquid there is only one which has not been congealed by the abstraction of heat, and that is alcohol, or spirits of wine.

We can only argue by analogy, that the bodies which exist in the gaseous state can be reduced to liquids or solids: which leads us to suppose that the substances known as atmospheric air, oxygen, hydrogen, &c. are, in fact nothing but the steam of various substances which cannot exist in the liquid state upon the surface of our globe without being deprived of a large portion of heat. This analogy has been confirmed by recent experiments and discoveries, particularly by those of our distinguished countryman Farrady. Neither steam nor any gas can be reduced to a liquid by compression alone, however high the degree of compression applied to it, notwithstanding the assertions of superficial writers, and even of some who are otherwise well informed, on the subject. But if, by the compression we could squeeze out the heat from these gaseous bodies, we could then liquify them. Dr. Farrady has substantiated this by actually converting several gases into liquids. For instance: he found, that when carbonic acid gas was submitted to a pressure of 1000 lbs. on the square inch, it became a liquid. It must, however, be remarked, that as the pressure is increased, the temperature is raised; and it is not until the gas is cooled that liquid is produced. These facts, united with the other analogy, afford such a high degree of probability, that, to a reflecting mind, there can be no doubt that every substance, in parting with its heat to a certain extent, becomes a solid; and it is possible to conceive that if, by any circumstances, the temperature of our globe were raised sufficiently, the water of the ocean would no longer be able to exist in a liquid form, but would assume the state of vapor, and mix with the atmospheric air. By the same cause, many of the solids would be converted into liquids, and fill the body of the ocean, so that we should have an atmosphere of steam, and an ocean of metal—a gold and a silver sea. Then, again by the process of evaporation, which causes liquids to pass into vapors, we should see the fable of Jupiter descending in a golden shower illustrated in golden and silvery showers. To carry the analogy still further; we know that water cannot exist in a liquid state at the poles. A slight decrease in the temperature of the globe, on a change of distance of the sun, would cause all the water of the earth to become solid; a further decrease would freeze the various gases, so that the air would drop down, and form an ocean of water; and a still further reduction of temperature would convert it into a solid body.

These circumstances suggest to a reflecting mind the beautiful adaptation of the different objects on the globe to each other, and the distance of the earth from the sun. Otherwise, those substances which ought to be liquid, for the sustenance of animals, would subsist in the solid state. It is not at all improbable, that the different planets have different substances in them, suitable to their distances from the sun; for there is no doubt that the temperature is produced by the sun, and depends on the sun's distance from the planets, and its intensity is diminished in proportion to its distance. In the planet Jupiter, the heat is twenty-five times less than it is with us; and water, on such a globe, could not exist in a liquid state, unless heat was supplied from other causes than the sun.

When we consider the prodigious mechanical power which has been obtained, by the mere ability, on our part, to convert a liquid or water into steam, and reconvert that steam, into water; when we consider the enormous amount of human civilization which has been produced by the due application of this simple physical effect; when we consider, that it is probable that the relations of the human race may be altered and modified by this application, and the very distances of the different parts of the world be changed by a speedy intercourse, and the prices of the objects of consumption be ultimately affected by it; when all these effects are attained by the mere fact of our availing ourselves of the simple physical effect of converting water into vapor and back again, we naturally say, where there is so large a field, and so many different substances from which the effect may be produced, should we not expect, from the large advances which are making in the generalization of these principles, that this effect may be produced from other substances. Water possesses several properties which render it the most hopeless and unfit for such an experiment. In order to convert it into vapor, we, of course apply heat. The least promising liquid is that which requires the largest application of heat; and, of all liquids, water consumes the largest quantity of heat, requiring 1000 degrees to raise it from a boiling state to a state of vapor: therefore, *a priori*, a philosopher would say, try spirits of wine, or a thousand other things, but do not try water, for this special reason. It may be said, that the cost and difficulty of producing any species of vapor does not depend upon the fuel necessary to produce it, but on the cost of the liquid itself. Supposing, then, we could get fuel for nothing, still water is the most unfit and unpromising agent. For instance: in the transport at sea, the source of heat is derived from coals, which are bulky, and are transported in the vessels in order to produce steam; the water at sea costs nothing: and, suppose the fuel cost nothing, still they must be carried, and they impose a limit to the application of the steam engine to the purposes of navigation. A vessel impelled by steam-power of 200 horses consumes one ton of coals per hour, or twenty-five tons per day: therefore, to provide for a voyage of twelve days, it would have to carry with it twelve times twenty-five tons of coal. Thus, therefore, there is a limit to the application of steam navigation. It is generally understood, that a vessel cannot carry more fuel than is necessary for the purpose of propelling it ten or eleven days; consequently, by the present steam impelling power, such a voyage as from Liverpool to New York could not be made for any practical and advantageous purposes.

In considering the prospects of improvement in these respects, we naturally look towards those liquids which are most readily turned into gaseous form. Ether and alcohol are easily converted into vapor, but in the way in which the steam power has been applied these liquids are rather expensive. If it was used in a high pressure engine the vapor would escape into the air and be lost, whilst, in a condensing engine, although not lost, it would be mixed with so much water that its separation would be attended with a considerable expense. There is only one other way in which it is possible to use alcohol, namely, by condensation, in contact with a cold surface. If we introduce the vapor of spirits of wine into a thin shell, formed by two bodies placed upon one another, after working the engine, it will spread over the cold surface of the hollow shell, the steam will be reconverted into a liquid state, and trickle out at the bottom, so as to be warmed over again, and this might be carried on from time to time.

But this great step must be followed by another improvement in the steam engine, especially for the purposes of transport both by land and by water, which will doubtless be cultivated in our own time. It is the application of the gases, and especially of carbonic acid gas. in a liquid form. If we could obtain carbonic acid in sufficient quantity, and on sufficiently moderate terms, there is no reason why it should not be employed to supercede steam at the present time. This gas takes the liquid form at the common temperature, under a pressure of 1000 pounds, and in that state exerts a prodigious power, and from its small bulk, would effect a saving of tonnage. The difficulty to its adoption lies in the price of the liquid, the providing of proper air-tight valves and pistons, and in guarding against the corrosion which the carbonic acid would cause in the materials themselves. But all these are matters of detail, and are at present but temporarily difficult, and we may, therefore, look forward to the superceding of coals altogether in the steam engine, by the use of the liquid carbonic acid, as nothing would be necessary except to send it into the receiver, and let the piston of the engine work as with steam; possibly it might be found expedient to apply heat, but a trifling degree only could be applied, as the power of the gas is so great that it has no bounds. Thus we should get rid of the magnitude of the marine boiler, and a thousand other inconveniences which attend it. We may, therefore look forward to the time when we may send our captains to sea with the wind that is to blow them in their waistcoat pocket; and it is not impossible, that we may get rid of those ugly smoky chimneys! which are at once so unpoetical and unpicturesque, and against which our sailors so bitterly complain, because they deface the surface of our beautiful sea.

OPERATION OF THE FENCE LAW ON THE POOR.

To the Editor of the Farmers' Register.

Brunswick, May 1st, 1835.

Although my experience or success will perhaps not justify any attempt by me to enlighten our people on the subject of agriculture, I am still induced to hope from every day observation, that I may say something which will be of service to some one individual, who might be more active, and exert more influence in behalf of our own old Virginia.

Mr. Editor, it is not enough for me, to hear that a man is a patriot—he must be a *Virginia* patriot. Have we not great reason to doubt the patriotism of our political editors, when we see room, and to spare, in their papers, (if we are to judge from the trash which they sometimes present to us,) and not one single extract from your invaluable paper? Are they afraid of infringing upon your rights, or do they believe that your paper, (as good as all of them acknowledge it to be) is taken by all of our citizens? Or are they so absorbed in the subject of politics, as not to see that it would benefit rather than injure your paper? Or are they indeed enemies to the formerly sturdy and honest, but now withering and disreputable agriculture of this good old commonwealth? I would not charge them with want of patriotism, or with being enemies to the cause of agriculture; but I would charge them with a heedless forgetfulness of the best interest of our people.

There is an old proverb frequently used to prevent poor people from marrying, that "when poverty comes in at the door, love will jump out at the window," which although not always true, is somewhat applicable to patriotism. When poverty comes in, patriotism, I was going to say, would take its departure, but at all events I will say, we see daily the hardy yeomanry of our state, when they begin to feel the secret but chilling blight of penury creeping in upon them, after a long and desperate struggle between patriotism, and the want of bread, yielding to the imperious requirements of the first law of nature, and with almost bursting hearts, bidding farewell to the land of their nativity to seek a home in a more plentiful country.

But sir what is the remedy for this state of things? You will say, improve our lands and the people will not move. But how are we to improve our lands? In many ways, which our people will not listen to, but which they might be induced to attend to if proper means were used. Cannot the press throughout the state be enlisted, to encourage agricultural societies—to call upon enlightened practical farmers, when they are *electioneering*, if at no other time, to give their more uninformed neighbors some new notions on farming, and whilst they enlist their feelings in favor of the candidate of their choice, enlist them also on the side of agriculture—which is to injure no party, but enable them to enjoy more perfectly the blessings of civil liberty in their native land. Mr. Editor, I differ from you, if you think your paper alone sufficient to bring about an entire reformation in a short time.* There are a great many of our good citizens who take political and other papers who do not take yours, but who might be induced to read communications in your paper upon the recommendation of their favorite political editor. But there is one subject particularly on which we need the aid of the press generally and that is the present fence law. We would not ask them to join us, but only to call upon the people to examine the subject fully and impartially, but particularly that the poor would look into it—for lately it has been objected that the poor would be oppressed by the alteration. And when I took my seat to write it was mainly to say something on the subject of the fence law, as oppressive to the poor. And although you may be tired of my stuff, I will try and give you some of my notions on that subject.

I take it for granted that the richer class of the community ought generally, as they have the means, to be the most enlightened; and if so, they will very readily see the propriety of uniting in support of the proposed alteration: unless indeed they, or some of them, see the benefit which the poor would derive from it, and be unwilling that they should receive and enjoy that benefit. I have the charity to believe that there are very few, if any of that sort. But that it would not oppress the poor, I shall try to give a few amongst a great many reasons. I will start with this self-evident proposition, that it requires half as much fencing to enclose a square of one hundred acres of land that it requires to enclose a square of four hundred. The richer man has a tract of land of eight hundred acres, half of which, is arable land; the poorer man has a tract of two hundred acres with the proportionate quantity of one hundred acres of arable land. The richer man has twenty hands on his farm, the poorer the proportionate number of five. The poorer man, (I use the comparative degree as one would not be considered very rich or the other very poor,) has to perform annually with one-fourth the hands half the labor in fencing that his richer neighbor does: and the richer man has to cut annually twenty acres of his wood land for the purpose of fencing with his twenty hands whilst the poorer has to cut, not

* Most assuredly we hold no such opinion—and none could be more absurd, at least while our subscribers do not amount to a fiftieth part of the farmers, even in Eastern Virginia—and perhaps bear no greater proportion to the number of those who read party politics, and almost nothing else—a kind of reading, which alone, and especially when (as is usual) confined to one side, teaches more falsehood than truth, and results more in ignorance than knowledge. In reply to a previous observation of our correspondent—so far from considering the extracting for republication from this journal, however frequently or copiously, as "infringing on our rights," it would be highly gratifying: and whether beneficial to our private interest or not, it would be greatly aiding whatever the Farmers' Register can do for the service of agriculture. But the true and sufficient reason for extracts being so seldom made by our brother editors, is simply this: their object is to make their papers as agreeable as possible to their readers and patrons—and to the great majority of them, subjects of party politics, and their usual accompaniments and embellishments, are the most pleasing. The censures of our correspondent then should be bestowed on the general taste of readers, even among the agricultural class, and not on the editors who minister to their pleasure, and aim to supply their intellectual demands.—Ed. Far. Reg.

five acres in proportion to his hands, but ten acres, since he has half the fencing to do which the richer one has to perform. But pursue the consequences: the poorer man in half the number of years has been obliged to cut down all his wood land, and the richer one by the same necessary course has only cut down double the quantity which the poorer has cut, and has still a good chance of woods left. And now see the condition of the poorer man compared with his richer neighbor. His neighbor having had less fencing, cutting, mauling, and hauling rails to do, has had more time to improve his land, (which improvement has been much less in consequence of the present law,) has in some sort gotten along in the world, and perhaps has a little money; whilst the other poor man, from the want of timber, is obliged to sell his land. His farm is now in market without a rail tree upon it. Who are the bidders? not his neighbors in moderate circumstances—no, they cannot buy for the same cause that has brought him to want, and because the land has no timber; but his richer neighbor, without an opponent, buys it at his own price, because he can open the wings of his fence and easily enclose so small a piece in a body with a large one; and the poor man is forced to leave all that is near and dear to him, and seek a home in a new country, not more highly favored than originally our beloved Virginia. And there is another view of the matter; the poorer man, from the weakness of his force, and the over proportion of his fencing, is apt to neglect his fence, and his richer neighbor's stock, four times as large as his own, break in upon him when he is perhaps from home, and destroy half his crop in one day—and then the falling out that takes place not only between them, but perhaps half the neighborhood are engaged in this dispute. Do you not perceive by the above named course, that the circumstance of our state being cut up into small tracts of land, has, under the present law, either driven from us the hardy yeomanry of the country, or brought upon many of them such abject poverty, as to render them very useless citizens; and that Virginia has principally been impoverished by the same circumstance, and its consequences. Thus, if the above reflections are sound, we see that the poorer a man is, the more oppressive in proportion is this odious law.

It may be objected that there are some so poor as to own no land at all, and that this rule will not apply to such. But how many poor have we who could rent and would cultivate a piece of land, which they might get for a very small sum, if it were not for the cost and labor of enclosing it; and how much waste land would the poor be allowed to cultivate, merely for the sake of having a small piece of meadow cleaned up for the proprietor, which meadow would yield the tenant an abundant supply of provender for all his stock. But Mr. Editor it is not for me to use such little arguments to trouble you—but our object should be to induce the people to attend to us whilst we give these arguments by word of mouth.

WAQUA.

From Dublin Medical and Chemical Journal.

INTRODUCTION OF FROGS INTO IRELAND.

It is not generally known that the introduction of frogs into Ireland is of comparatively recent date. In the seventeenth number of the Dublin University Magazine, there is a quotation from the writings of Donat, who was himself an Irishman, and Bishop of Fesulæ, near Florence, and who about the year 820, wrote a brief description of Ireland, in which the following passage occurs:—

> "Nulla venena nocent, nec serpens serpit in herba;
> Nec conquesta canit garrula rana lacu."

"At this very hour," says our respected contemporary, "we have neither snakes nor venomous reptiles in this island; and we know, that, for the first time, *frog-spawn* was brought from England in the year 1696, by one of the fellows of Trinity College, Dublin, and placed in a ditch in the University park or pleasure ground, from which these very prolific colonists sent out their croaking detachments through the adjacent country, whose progeny spread from field to field through the whole kingdom. No statue has yet been erected to the memory of the natural philosopher who enriched our island with so very valuable an importation of melodious and beautiful creatures." We may state, however, that we have learned from good authority, that a recent importation of snakes has been made, and that they are at present multiplying rapidly within a few miles of the tomb of St. Patrick.

THE INJURIOUS EFFECTS OF HEAT ON CULTIVATED LAND.

To the Editor of the Farmers' Register.

Fauquier, April 21st, 1835.

In two communications I addressed to you in February last, I stated that *"heat is a great destroyer of the vegetative or nutritious principles of the earth."* So far as I then knew, or now know, that opinion is peculiar to me. Its novelty, and the rational deduction of the fact from the premises, justified its publication, in the double hope of establishing its truth, or of exposing the error. Mr. James Fife has contested its correctness; and while I have neither leisure nor inclination to discuss, with labored minuteness, my own opinion, or his replication, I will proceed to make a brief reply.

Mr. Fife says, in submitting "some difficulties that lie in the way of my proposition and illustration," he could, "for example, select lands in the torrid zone, exposed to the heat of a vertical sun, and producing large crops, notwithstanding the frequent stirring in the hottest time. How is this, if the sun kills the nutritious principles of the earth?" It is said there are exceptions to all general rules, and correctly. Mr. Fife may know of some land in the torrid zone which produces "large crops, notwithstanding the frequent stirring in the hottest time;" but, I marvel greatly if such be the fact. Let it be borne in mind that I have not said that one crop, or two, or ten crops of corn, tobacco or any other plant, would in every grade and variety of soil produce effects equally injurious. I did not, and could not say, that rich river low ground would be exhausted as soon as poor river hills. The poorer land is, the easier is it reduced to sterility. Now, it must be obvious to the capacity of every man, that land under the torrid zone which has been often cultivated and still produces good crops, must have been, originally very fine, or have been made good. If it was originally good, I venture to say it is now worse, unless improved by art. Will Mr. Fife say, that, after repeated consecutive cultivation by that minister of desolation, the shovel plough, it is as good as when first the forest was felled? Can he venture such a declaration in the face of the whole earth? The testimony of every man—of every "beast that bites the grass or browses on the shrub" will confront and confound him. I will not attempt to prove what is universally known to be true, that all land—land of every grade of fertility, of every geological base, from barren sand to the deep and inexhaustible beds of alluvion on the shores of the Mississippi, deteriorates under the cultivation of corn, cotton, tobacco and other spring crops, which require the earth to be kept pulverized until the plant is matured. But, it deteriorates in a greater or less degree as the land is poorer or richer. The thin soil of sand hills vanishes in the third crop of corn, cotton or tobacco; while the soil of the Mississippi, the Red River, the Yazoo or Big Black, twenty feet deep, cannot be exhausted till the bottom be reached; for as the vegetable mould of which it is composed sinks beneath the exhausting action of the sun, the plough descends with it to a bed not heretofore disturbed. It may be, that land in the torrid zone, of the same base, is not so much injured by cultivation as in our latitude. The rains of that region are more frequent, and dews manifold more copious than in Virginia The moisture of a southern atmosphere is, also, a part, and a leading part of its natural history. Here our summers are dry, and the sun more intense than far south of us. They are, at stated hours of the day, refreshened, by steady breezes from the sea always charged with invigorating salt-water vapor; and at night their copious dews impart a delightful coolness to the air. Here we have, occasionally, slight breezes—generally dry; slight dews till late in the summer, and hot nights. In the north the land is not galled as here, in part owing to three causes about equal in their effects:—the sun affects us two months longer in the year than it does them—their land is better cultivated, and there is no negro labor to beget idleness and its handmaids, shovel ploughs, new hopes and disappointed expectations, rags and debt.

It is known to all, that one of the principal means of improving worn out land, is the mould-board ploughs, the bar-shares of my friends and countrymen, McCormick, Stewart, Kemper, Fletcher and Green. The benefit is derived, in my opinion, from various causes. The earth which has been exhausted by the sun is turned under, where it is kept till the next fallow, while the loam or other soil never before reached by the plough is thrown to the top, where, from the action of the sun, rain and atmosphere, noxious principles are expelled or neutralized, or those that are valuable are imbibed. I suppose that Mr. Fife did not understand me to say, that the sun, in all the degrees of its influence on the earth, is injurious.

All crops that require frequent ploughing in the spring and summer, corn, cotton, tobacco, turnips, &c., have the character of exhausting crops, when others that yield as much in weight are known not to impoverish the ground: for instance, wheat and rye. If it were not the mode and period of cultivation that does the injury, principally by exposure to the sun, all crops of equal weight would reasonably do equal harm. The universal testimony of experience is, however, that corn, cotton, tobacco and turnips, are exhausting, and, that wheat and rye are improving crops. What other cause than the mode of cultivation can induce so great an injury? The repeated ploughings, erroneously deemed to be necessary to make these crops, renders the earth so light or loose as to receive the heat of the sun to the depth of the ploughing. The top earth is most injured because most exposed to the sun, and after it has been subjected to his rays for some time, another surface is thrown up by another ploughing, and so on, till the whole body ploughed for corn, &c. is successively operated upon, and finally, the whole is left open for years before it regains its former compactness. Clay from the bottom of wells, cellars, &c. after a few years produces luxuriantly.

As to Mr. Fife's notion that the mixing of water with earth destroys the fertility of the earth, I can say no more, than it is the first time I ever heard that water was not a valuable, nay, an indispensable agent in the growth of vegetables. Heat is also indispensable; but too much of either destroys vegetable life; and "mortar" contains too much of the former. It is true, that by mixing water and earth more intimately than by the usual falling of rain, when dried it is harder; but no other injury can be done by the admixture. If it can, the more rain the greater the injury; and what then becomes of the well established fact of the fertilizing properties of water? The bottoms of rivers and ponds too would be very poor instead of being very rich. Roads that have been used for seventy years, although trampled thousands of times more than mortar for bricks, it is every day's practice to reclaim by the usual methods of improvements. Let me here make the conjecture, that if the dust of hard burnt bricks be subjected to the same means of improvement with well trodden roads or dried "mortar," that the end will be a thorough conviction of the impracticability of the one, and the easy accomplishment of the other.

Mr. Fife is respectfully advised to visit north Alabama, (the great bend of the Tennessee,) a country of as high reputation for fertility, a few years ago, as any in the south, and see for himself, its present thriftless condition. Originally, indeed, not more than fifteen years ago, very rich, of dark red loam, with a surface among the most beautiful and convenient for the purposes of agriculture on earth; the effects of the sun upon it, exposed as it has been by shallow ploughing, have been ruinous. Corn and cotton have thus ruined that, as corn and tobacco have this country. Again let Mr. Fife go into the Dutch settlements of Rockingham, Shenandoah, Loudoun: to Pennsylvania, New Jersey, and New York, where they have to a very small extent cultivated corn; where wheat and rye are the staples and are produced abundantly, and he will see the difference between those regions, and the land of corn, tobacco, and cotton.

It is generally thought that the hickory, lombardy poplar, &c. exhaust the earth, and that the yellow locust improves it. The instances cited are where the land is cultivated in corn or other spring crops. The earth under the former is generally exhausted where it *is cultivated;* but not so under the latter. The reason is that the roots of the former are much more shallow than those of the locust, and of course, the ploughing is not deep. The body of earth thrown up by the plough under the poplar and hickory, is not half so deep as under the locust, and the power of the sun is proportionally greater on it. Who is he that can point out the difference in the fertility of the ground well covered by grass, where the largest poplars and locusts have grown for many years in the same yard? The earth under trees, whose roots are shallow, is merely scratched on the first ploughing, and from the repetition of it appears to be dead or exhausted; while under the locust, the apple, the peach tree, &c. &c., whose roots are deep and not reached by the plough, its advances in improvement are at least as fast as where there is not a tree.

My communication is growing too long, and whatever other views I have, must, if at all, be forwarded to you hereafter. Such as are here thrown together depend rather on the experience than the theories of men.

J. R. WALLACE.

From the Genesee Farmer.

THE BUFFALO BERRY.

Last autumn we procured of Judge Buel, three trees of the buffalo berry; and this spring when they came into flower, we found that one plant is *staminate* and the other two *pistillate.* This discovery is very gratifying; for it is well known that like the date palm, none of these trees are expected to be productive unless both sexes grow in the same neighborhood. Whether there is any way to propagate them except by the seed, we have not been informed. Last year we tried *layers* on another plant which we had previously obtained; but none of them rooted. If it could be increased by some such mode, we could then be certain of having both kinds; and we should not be subjected to the risk of having only *one* sort when we procure *two* trees. If they can be readily increased only by seeds however, it will be well to purchase only such trees from the nurseries, as have had blossoms; and as these appear while the trees are small, this precaution will not be attended with much inconvenience. Ours are not five feet high.

From the Genesee Farmer.

THE OSAGE ORANGE.

We have been informed that this fruit ripened the last season for the first time, east of the mountains. Our friend T. S. Pleasant has kindly supplied us with seeds from his trees at Beaverdam in Virginia; and we have now a number of plants which sprung from them in a hot-bed. They germinate freely.

This tree is also *diœcious.* We have a pistillate plant eight or nine feet high, which now appears to be preparing to blossom; but as this is the only tree of the sort in our possession, we cannot expect much fruit—which however is only to be prized as a curiosity, or as the means of propagation. Pistillate trees indeed, sometimes produce hermaphrodite flowers, and consequently some fruit; but never in much quantity; and this exception to a general rule, seems only to be a provision of nature for preserving the species under extraordinary circumstances.

With *layers* of this tree we have always been unsuccessful; and equally so with *cuttings* of the branches, though we have succeeded with pieces of the root. Whether we shall hereafter become more skilful or not, is uncertain, but at present we are inclined to believe it can be most readily increased by the seeds.

From Jameson's Philosophical Journal.

SUBTERRANEAN LAKE AND ITS INHABITANTS.

"The most striking example which we can mention of a subterranean sheet of water, of a varying level, is that of the Lake Zirknitz, in Carniola. This lake is about six miles long by three broad. Towards the middle of summer, if the season be dry, its surface rapidly falls, and in a few weeks it is completely dry. The openings by which the waters retire beneath the soil may then be distinctly perceived, sometimes quite vertical, and in other places bearing a lateral direction towards the caverns which abound in the surrounding mountains. Immediately after the retreat of the waters, all the extent of the surface which they covered is put under cultivation, and at the end of a couple of months, the peasants are mowing hay, or reaping millet and rye, in the very spot where, some time before, they were fishing tench and pike. Towards the end of autumn, and after the rains of that season, the waters return by the same natural channels which had opened a passage for them at the time of their departure. The description which we have just given of the inundations and retreat of the water, is the regular and common occurrence; but every extraordinary atmospheric change is apt to interfere with this order. Sometimes a very heavy fall of rain on the mountains with which Zirknitz is surrounded occasions an overflowing of the subterranean lake, which advances, during many hours, so as to cover with its waters the land which lies over it.

"Very singular peculiarities have been remarked as belonging to these different openings in the earth: some of them supply nothing but water; others supply a passage both to water and to fishes of a greater and smaller size; and there is a third class by which ducks are supplied from the subterranean lake.

"These ducks, at the moment that the water floats them to the surface above ground, swim with perfect facility. They are completely blind, and almost naked. The faculty of sight, however, is very speedily acquired; but it is not till after two or three weeks that their feathers, which are black, except in the head, are so grown as to allow them to fly. Valvasor visited the lake in 1687. He himself caught a great number of these ducks; and saw the peasants catch individuals of the *Mustela fluviatilis*, which weighed two or three pounds, tench of from six to seven pounds, and, finally, pike from twenty to thirty, and even to forty pounds weight. Here, then, it will be perceived, that we have not only an immense subterranean sheet of water, but a real lake, with the fishes and ducks which frequent the common lakes of the country."

For the Farmers' Register.

REVIEW.

Survey of the tide-water region of Maryland, and report thereon, by J. T. Ducatel, *8vo. pp.* 61. *Document published by order of the Legislature of Maryland.*

The legislature of Maryland has latterly, in several important matters, exhibited a rare and laudable degree of attention to the general improvement of that state—and the means adopted to forward that great end, are manifestly not planned in subserviency to any narrow minded feelings of sectional jealousy, but are dictated by a liberal and patriotic disposition to use the means of all, for the general benefit of all. May the results be fully commensurate in reward with the enlightened acts and liberal means employed, and with the noble spirit which has prompted them.

Among the several means for promoting "internal improvements"— (a term generally, and with a singular degree of incorrectness confined in the United States to making roads and canals—) one of the least costly, and which was probably considered as of least importance, was directing to be made a geological survey of the territory of Maryland. But it may well be doubted whether the future benefits of a well conducted examination of the mineral treasures of the state, the making known all its dormant resources of wealth, and the instructing its citizens as to the manner of reaping such rewards, might not yield a richer harvest, than even the millions of dollars bestowed upon its magnificent canal and railway. And even if the actual plan, and consequently its execution, be defective, the benefits to be derived, though produced indirectly in a considerable degree, will nevertheless be of great value. We shall make free to point out what appear to be some of the defects either of plan, or of execution: and this freedom will be used the more readily because of the high value attached to the general plan, and the anticipations of beneficial results from its execution, so far as it has been completed, not only to Maryland, but to her sister states—to whom, in this respect, she has offered an example already followed by Virginia, and which will doubtless extend farther.

The most important and most abundant substance, by far, among the mineral resources of wealth in lower Maryland, is the immense underlying deposite of shell-marl. Accordingly, the various beds, their localities, qualities, and practical value as manure, constitute the greater part of the matters embraced in the report. This exhibition cannot fail to increase the zeal and industry of the farmers who have already been deriving profit from this manure, and to attract attention from, and invite to similar efforts, the still greater number who have heretofore possessed this resource of wealth without knowing or enjoying its benefits: and persons elsewhere will also learn to attach a more correct estimation to the great improvable value of this highly favored, and yet heretofore neglected and undervalued region—abused as in Virginia, both by the opinions of strangers, and by the practices of its cultivators.

The report has so far only embraced the tide-water region of Maryland, and the remarks on it which it is proposed to offer, will be confined to the most important object of investigation—the beds of marl. The results of the geologist's own observations will be copied at length.

"*Southern limits of the shell-marl deposite on the Eastern Shore of Maryland, available for agricultural purposes.*

"There is reason to believe, as stated in a previous report, that this shell-marl deposite underlies the whole of the country between the Delaware and Chesapeake bays, even to its extreme limits; but, as was also previously observed, it evidently inclines on the Chesapeake side, from the summit level of the peninsula to the water's edge. The dip of the formation is at an angle of about 5° from north-east to south-west. The inclination is not, however conformable to, though in the same direction with that of the country; a circumstance which it is important to attend to, as a neglect of it might cause fallacious expectations to be entertained of the discovery of marl in situations at its north-east extremity where it lies too deep, for profitable extraction; and, on the other hand, might dissuade from a justifiable research in situations at its south-west extremity, where though lying low and the country flat, it still may be found at a small distance only below the surface of the soil. It is likewise necessary to bear in mind what has already been said on a former occasion, that the surface of the marl deposite undulates; so that, it not unfrequently happens that the opposite banks of an inlet, present to view the summits of two waves of marl, so to speak, the trough of which constitutes the bed of the creek.

"Observations so far made seem to indicate that south of the Choptank, in Dorchester county—in the lower portions of the county—the marl in general lies too low to be advantageously extracted. It has been reached in the sinking of wells; but the only place where any indications of it present themselves above tide, is on the Choptank, west of Cambridge—at a spot called Sandy Hill. The material alluded to is covered by a stratum of sand from fifteen to twenty feet, contains impressions of scallop, clam, and other shells, and was observed in the high banks of the river, from the spot just named to beyond Castle-Haven. Subjected to analysis it was found to consist of carbonate of lime 23, silica 58, alumine 13, and a small proportion of iron. This is no doubt a continuation of the shell-marl deposite of Talbot county; and as no other indications of marl have been observed south of the Choptank, in Dorchester county, it may probably be assigned as the limit of that deposite in this direction. It is not pretended however, to exclude by this assignation the upper parts of said county which have not yet been examined.

"*Principal location of the shell-marl deposites between the Choptank and Chester rivers.*

"These deposites are in Caroline, Queen Ann's and Talbot counties, and will be most conveniently indicated under the head of each county.

"*Caroline county.*—At the head of the navigation of the north-west fork of the Nanticoke, at Federalsburg, there is a deposite of marl which lies high, and in a very accessible position; it owes its formation to an accumulation of fossil oysters, and other small marine shell-fish, some of them extremely delicate, giving evidence by the integrity of their parts that they have originated and died where their testaceous coverings are now discovered, and appear to have been subsequently enveloped in a deposite of clay. The material of this deposite may emphatically be called *shell-marl:* the enveloping clay contains from fifteen to twenty per cent. of calcareous matter, and the chief constituent of the fossils is the same fertilizing agent. The soil of the surrounding country is principally a light sandy loam; so that the marl which has just been described consisting principally of carbonate of lime, and aluminous particles, is no doubt admirably fitted to impart to it the physical and chemical properties requisite to constitute a good soil.

"At Greensborough, the marl forms the substratum of the soil upon which the village is built. It breaks out on the west bank of the river, a few feet above tide. At low tide, it becomes very accessible, and from the nature of its constituents, as exhibited in the appended table, showing the result of the chemical analysis of the marls from the several localities in Caroline county, and the condition of the superincumbent soil, it will be perceived, that it must furnish a material of great value for the improvement of the latter. Reference must be made for the analysis of this marl, to No. 1. of the table.

"At Denton, or rather in its vicinity, several localities of marl were discovered, principally on the head streams of Watt's branch. They are generally, of excellent quality, and well adapted to use on the spots and in the vicinity of where they occur. See Nos. 2 and 3 of the table.

"Three miles below Denton, on the east side of the Choptank, there occurs a considerable deposite of fossil oysters, forming the mass of the banks of the river, from fifteen to twenty feet above tide. The neighboring country would derive great advantage from the general use of this material, and every consideration of individual interest and public usefulness, was accordingly presented to the proprietor of these valuable banks to induce him to employ their contents on his own lands, or dispose of a portion of them to neighbors willing to purchase. It is to be believed, that an intelligent citizen cannot long resist any proper appeal made to him, when conducive both to private interest and to public good." pp. 14 to 17.

This appears to be saying indirectly that the "intelligent citizen" had to that time not only refused to use manure from this inexhaustible body, but to permit it to be used by his "neighbors willing to purchase"—and it is only "believed" that "he cannot long resist any proper appeal made to him when conducive both to private interest and public good." If this is the meaning of the passage, the compliment to the marl bank and its owner is equivalent to a strong expression of deserved contempt for the latter.

"Another much more extensive, and more decidedly marly deposite, occurs on the estate of General Potter, at Potter's landing on the Choptank, between Kokias creek and Watt's branch. It affords several varieties of marl, (Nos. 4 and 5.) It is covered by a blue earth, which on analysis yielded the following constituents: alumine 10; carbonate of lime 9; silica 70, &c. This article might also be advantageously employed as an amendment to the soil by which it is overlaid; it is, in fact, a sandy marl. The enlightened and patriotic proprietor of this estate, has expressed his willingness to supply his neighbors with such quantities of these materials, as would afford them the means of satisfying themselves as to their efficacy." p. 17.

The owner of marl has as good right to sell it as any other commodity—though in some other places it is a thing unheard of for any man having an inexhaustible supply, not to *give* it freely to his neighbors. But it is a strange waste of encomium to speak thus in commendation of this "enlightened and patriotic proprietor" merely for having "expressed his willingness to supply his neighbors with such quantities as would *afford them* the means of satisfying themselves as to the efficacy" of his marl—that is, to let them test its value for his own future benefit.

"In the neighborhood of Hillsborough, marl of very good quality has, likewise been discovered.

"*Queen Ann's County.*—An important and valuable deposite occurs at the head of south-east creek, in the vicinity of Church Hill. It is found on a farm belonging to Judge Earle; at present, the residence of Walter J. Clayton, Esq. by whom it was made known. Its analysis is given at No. 6 of the table. Similar deposites may be expected to make their appearance at the heads of the several creeks, having a common estuary with the one just mentioned; namely, Hamilton creek and Island creek. Accordingly, an analogous deposite has been traced in the direction of the head of these creeks, to the north-east side of Corsica creek, reaching into that section of Queen Ann's county, known as Spaniard's neck.

"On the south-west side of Corsica creek, extending to the head of the branch south of Centreville, the marl is abundantly diffused. Nos. 7, 8, 9, 10, 11, 12 and 13 indicate the constituents of the various kinds found in this region, the samples of which, have been furnished by the gentlemen whose names are given in the marginal column of the table.

"Continuing in the same direction, being in a line north-east and south-west, to the head of Reed's creek, marl of superior quality (No. 14,) is found on the estate designated, as belonging to Maxwell's heirs. It is composed principally, of that variety of fossil shells, known in popular language, as *pearl shells* (*Perna Maxilla.*) These broad, thick shells, closely compacted together in the deposites, exfoliate, and crumble into almost an impalpable powder, by the least exposure to the air. They thus yield readily and abundantly, their calcareous particles to the soil.

Finally on Back Wye, where abundance, goodness of quality, and a judicious application on the part of those who are so fortunate as to possess the material, have co-operated, the most extensive benefits have already been realized. Nos. 15, 16, 17, 18, 19 and 20 of the table, indicate the chemical analyses; fossil constituents and localities of the marl in this section of the country. Nos. 21 and 22 indicate the constituents of two samples of shell-marl from Chew's island, taken from the estate of William Paca, Esq.

"*Talbot County.*—Nearly the whole of this county is underlaid by marl; but it presents itself under a variety of circumstances of unequal facilities for extraction, and is, as elsewhere, of very variable qualities.

"On the Talbot side of the Tuckahoe branch of the Choptank, it occurs in the high banks of the river from six to ten feet below the surface; but is exposed to view in the ravines that make down to the river. As every where else, it is undulating on the surface, occurring in a distinct stratum, from three to five feet in thickness, the inferior level of which, is six feet above high water mark; it is frequently covered by a crust of indurated marl mixed with sand, evidently caused by the action of the waters, which filtering through the loose soil above, on reaching the marl bed, have facilitated its decomposition, removing a portion of its calcareous constituents and depositing in their stead, silicious particles. The most remarkable deposite of this kind, is about three miles south of Hillsborough, on the farm of Thomas O. Martin, Esq.; a more interesting one, in every respect, can scarcely be pointed out in any other part of the county. In this place, the banks are elevated from thirty to forty feet above the river, and the deep ravines that descend to it, greatly facilitate the extraction of the material at all seasons of the year. This place may be mentioned as the only spot at which the bottom of the marl deposite is known to have been reached; unfortunately, the excavation was not sufficiently extensive to allow a satisfactory examination of its substratum; it appeared to consist in a stiff blue clay. The analysis of the marl from this locality, is given at No. 23 of the table.

"Descending the Tuckahoe into the Choptank, a little below Kingston, we reach the mouth of King's creek. The high banks on the inlet of this creek exhibit thick beds of good marl, (No. 24,) the shells of which are imbedded in a stiff clay. The bed at one locality—on the farm of Mr. William Pratt—is covered by a thick stratum of a very plastic chocolate-colored clay, which itself might serve as a useful amendment to the thin soils of the surrounding country.

"But perhaps the most valuable beds of shell-marl in this part of Talbot county, inasmuch as they may be made extensively available to the public demands for the article, are those which were fully described in the preceding report. They occur three miles below Dover bridge, forming the high bank from fifteen to twenty feet above tide, being one compact mass of fossil shells, and extending nearly a mile along the river, on the farms of the late Col. Smyth and Mr. Atkinson. These beds are in contiguous strata, apparently successive, and consist of vast accumulations, principally, in the ascending order, of oyster shells, succeeded by clam shells intermixed with other marine shells, scallop, clam and scallop, and uppermost principally of scallop. Endeavor was made to bring these beds into notice, with a view of enlisting them into the public service, by giving to their proprietors what was deemed proper directions for extracting the material, and salutary advice as to a just estimate of its value, in order to secure a constant and permanent disposal of it. The subject is now in progress of experiment. South of these banks on the Choptank, no other deposite of marl is known to occur." p. 19.

Several of the foregoing passages, in addition to many other incidental remarks through the report, exhibit in many of the land owners a degree of neglect and ignorance of the value of their bodies of fossil shells, which is the more strange and unaccountable, when it is considered that the first known profitable use of this manure was made thirty years ago in part of this region of country, (by Mr. Singleton) and that the example had been successfully followed on many other farms in Talbot and Queen Anne's counties. The practice has not to this day extended to the Western Shore of Maryland, where the means are unlimited, as is seen in a subsequent passage which will be extracted from this report.

The reader would naturally desire to know, but is not informed, whether the "plastic clay" mentioned in the last paragraph but one, is recommended for manure, supposing it to be *merely a clay*, or as containing other useful ingredients.

"It will have been remarked, that these deposites are described as lying high above tide. It is, in fact, from this boundary of the county, that the dip from north-east to south-west in the marl deposite previously alluded to, becomes most apparent: occurring so far in Talbot county, only a small distance below the surface of the soil, it now becomes covered in the middle districts by a heavy coat of gravel and sand, extending from north to south from the head of Wye to the Choptank, and reappears again at a lower level on the banks, at the termination of the numerous inlets that so conveniently and beautifully intersect the lower portions of the county.

"A reference to Map A, appended to this report, will convey a better idea of the extent and numerous localities of shell-marl in this section of the state, than a bare mention of them by name could do. Suffice it to say in this place, that a line drawn from the head of Skipton creek, touching the intervening creek between this and Dividing creek, and perhaps, prolonged to the Choptank, would limit the eastern boundary of that portion of the territory which embraces the great shell-marl formation of the county; whilst another line from the mouth of Pickering creek, enclosing the western banks of Mile's river as far as the ferry; thence, by the head of Plain dealing creek to the Choptank, and uniting with the water boundary of the county, would form its western limits. Nos. 25 to 41 on the table, indicate the chemical composition of the marls from the principal localities of this great deposite.

"*Nature of the materials contained in the shell-marl deposites of the Eastern Shore of Maryland.*

"It is important to become acquainted with the precise nature of materials contained in these deposites; because upon this knowledge in a great measure depends the judicious application to be made of them. It is more especially to furnish such information that the table which has been so frequently referred to was made out. Some general remarks under the present head seem, however, to be necessary.

"Perhaps the true nature of these deposites is this. They are vast accumulations of the exuviæ of testaceous animals, formed at a time when the portion of dry land where they are now observed, was the bottom of an ocean. There is no evidence that their present elevated position is owing, to any upheaving of strata from below—the favorite geological notion of the day —nor to a simple retreat of the water from above them. They are generally overlaid by a thick covering of water-worn materials, such as gravel and sand, occasionally enveloping boulders of rocks belonging to the oldest geological formations; sometimes they are covered by a heavy stratum of clay; occasionally by alternate strata of clay, sand and gravel. In no instance, save when they form the bottom of an inlet or creek, or when they occur in the bed of a stream, has their surface been observed to be denuded. Some cataclysm contemporaneous with the cause of the retreat, has no doubt, occasioned the formation of these superincumbent strata. It is not worth while however speculating about this, at present; although it may be useful to know that the material by which the marl is covered is not contemporaneous with the marl itself.

"It is useful to know this, for two reasons. First, to become satisfied that the nature of the superincumbent soil cannot in any case be expected to partake of that of the underlying stratum of marl; hence it is never found to contain calcareous particles. Secondly, to understand the cause of the variety in the ingredients with which the marl is associated; thus we find the shells sometimes enveloped in clay, at other times in sand, and then again in a mixture of sand and clay, these two ingredients being in very variable proportions.

"Now although the marl does not influence the nature of the soil lying over it, the latter frequently greatly modifies the quality of the marl beneath it. The cause of this is apparent. The superincumbent earth (understanding thereby the whole mass of materials covering the marl) consists either of clay, gravel or sand, or a mixture of all these, and having, it is presumed, been deposited upon the marl subsequent to its formation, it will, from a variety of causes, have become mixed with it. It is, however, more especially by infiltration that the marl becomes modified in consequence of the condition of the soil above it. If the latter contain fine particles of sand, as is very commonly the case, these will be taken up by the waters that traverse the soil, and so charged, will penetrate more or less deeply into the marl bed. Should the shells there be loosely scattered in their mineral envelope, which is also frequently sand, the whole of their calcareous particles may be dissolved and become replaced by a silicious deposite. The bed of fossils will in this case, at least in its upper portions, exhibit an accumulation of indurated *casts* alone of shells. Such is the case in many places on Chew's island, in some of the fossil deposites of Skipton creek, and in several places on the Wye. It is evident that then the material cannot be used as marl. When again, the superincumbent soil is ferruginous, it very generally happens that the shells are bound together by an argillo-ferruginous cement extremely hard, which unfits them for use not only in this respect, but also by substituting for the calcareous ingredient which they originally contained a predominating constituent of oxide of iron, which cannot be beneficial to the soil.

"It must be borne in mind, however, that this sort of disnaturing of the shell-marl is most generally confined to the upper portions of the deposite. Hence, if in the search after marl, those silicious or ferruginous incrustations are met with, they should always be removed to ascertain the nature of the material beneath. There is a very remarkable example of a thick coat of silicious incrustations covering very excellent marl, on the estate of William Carmichael, Esq. on Back Wye, Queen Ann's county.

"As to the fossil constituents of the shell-marl deposites on the Eastern Shore of Maryland they are very various. Some are principally composed of oyster shells, others principally of scallop, some again principally of clam, and in others nearly the whole bed consists of *perna*, commonly known by the name of pearl shell. These last furnish decidedly the best marl. The perna is a broad, thick shell, somewhat in the shape of a large oyster, of a white pearly appearance, peeling off in thin laminæ that are very soft and friable. When exposed to the atmosphere for a short time it falls into an almost impalpable dust, consisting essentially of carbonate of lime. This shell occurs in most of the marl beds of the Eastern Shore, but more especially in those of Talbot county, and as already stated, at the head of Reed's creek, in Queen Ann's county.

"The quality of the marl is also greatly influenced by the nature of the shells that compose it. It was stated in the former report, and may be repeated here, in illustration of what has to be said under the present head, "that those beds which consist principally of *clam shells*, usually associated with numerous varieties of other smaller bivalve and univalve shells, containing at the same time very little admixture of foreign ingredients, yield a marl which exhibits its beneficial effects upon the soil in a very short time; because the calcareous particles are derived from shells which are very prone to disintegrate when exposed to the atmosphere. Marl beds, composed entirely or principally of *oyster shells*, are much less valuable, because of the slow disintegration and decomposition of this species of shell. *Scallop shells* resist such decomposition still more obstinately than do oyster shells, and when they occur, as they have been observed to do, in extensive beds firmly agglutinated by an argillo-ferruginous cement, they are useless in all soils, and may be positively injurious to some."

"It follows then, that the nature of the material in the shell-marl deposites must be ascertained first in reference to the species of shells which it encloses, and their admixture with foreign ingredients, as clay, sand, gravel, &c. This can be done by a simple inspection aided by such experience and knowledge as can be acquired without any difficulty. But a more important consideration relates to the *composition* of the marl, and especially to the relative proportions of its three principal constituents, namely, carbonate of lime, alumine and silex. To ascertain this recourse must be had to a chemical analysis. The proportion of calcareous particles is doubtless generally the most important fact to be determined; but it sometimes becomes equally important to ascertain the proportions of aluminous and silicious particles; for, one of the advantages, and not an inconsiderable one, in the application of marl is its use in ameliorating the mechanical condition of the soil, and these ingredients are eminently serviceable in this way.

"From what has already been said, it will readily be perceived that great variety must also necessarily present itself in the chemical composition of the marl in its different localities. So far as experiments have been conducted, it has been found that the proportion of calcareous particles varies from 20 to 60 per cent.; that of aluminous from 10 to 20 per cent. that of silicious ingredients from 30 to 59 per cent.

"It is doubtful whether any directions could be given which would enable those unpractised in chemical operations and manipulations to ascertain with any degree of accuracy the relative proportions of these constituents of the marl. This is a subject which must be submitted to some analytic chemist; and it is the duty of the geologist to satisfy inquiries of that sort whenever called upon for that purpose. On the proposed geological map of the state, it is contemplated to express the composition of the marl in the principal localities that will be laid down; and by extending the table exhibiting the chemical analyses of these marls, to all such as can be conveniently procured, a mass of information will be collected that will in some measure supersede the necessity of any further experiments.

Though the words of the last three paragraphs, if very strictly construed, may be maintained to be correct, yet they will probably convey a very different, and as we think, an erroneous impression to most readers. It may be readily conceded that no "directions could be given which would enable those unpractised in chemical operations and manipulations, to ascertain with any degree of accuracy the relative proportions of these constituents of marl"—if "these constituents" are to be separated with absolute accuracy, as arranged in the table of marls analyzed (p. 61,) under the heads of "*silica*, *alumina*, *lime*, *carbonic acid*, *oxide of iron*, *potassa*, and *water*." To execute this separation correctly, would indeed require not only the labors of an "analytic chemist" but of one of a very high order of talent. If all Dr. Ducatel's analyses of calcareous marls were as carefully and accurately made, he has gone through a most laborious undertaking, and to very little purpose. But if this array of scientific terms and arrangement had not been brought forward, and served to create apparent difficulty, and the operation is confined to what is important and necessary to the farmer, the very opposite of the above opinion might be truly expressed, viz: that any person of ordinary intelligence may easily learn to analyze his own calcareous earths—and for all useful and practical purposes, with as much correctness as the analytic chemist. Farther—the results so to be obtained, would be even more correct than those of the author's analyses, on account of a defect in his mode of examination, which will presently be noticed more particularly. Such directions (for example) as are given in the Farmers' Register, Vol. I. p. 609, if attended to, will enable any one to analyze marl so as to know the amount of calcareous matter—and if desired, the proportions of silicious sand and aluminous earth, or pure clay, are as easily found. The two latter ingredients, however, would seldom require more nicety of observation than a glance at the residuum, as shown after removing the calcareous parts. The proportion of oxide of iron is still less important—(at least for any purpose yet known;) of "*water*" as a *chemical* ingredient of calcareous marl, our ignorance is readily confessed—but at all events, its presence cannot affect the value of the manure, except in adding to its useless weight. The column for potassa (potash) is a blank throughout the whole list of calcareous marls (being found only in the *green sand*, and not in calcareous marl proper,) and therefore is manifestly not necessary to be sought for in such marl. Then as to the main and all-important ingredient of marl, the calcareous earth, or carbonate of lime, an unnecessary obscurity is thrown over it by stating its amount in its two component parts of *lime* and *carbonic acid*, in separate columns. There is no reason for this, as these constituents always combine in certain and invariable proportions, to form carbonate of lime. But this is not known to every reader, and therefore the arrangement adopted keeps many entirely in the dark as to the strength of marl, and is even somewhat embarrassing and troublesome to the inspection of those who well know the proportions in which the constituents of carbonate of lime combine. If, for example, the marl marked 6 in the table, (p. 61,) had been stated to contain 38 parts of carbonate of lime, or shelly matter, in the 100, it would have been plain to every one: but as it is there stated to contain 21.25 of *lime*, and 16.15 of *carbonic acid*, it may be well doubted whether the information contained is not hidden from most of those interested in the report, and for whose benefit it was specially designed. Indeed, the constituent parts are improperly stated chemically, as well as for common and practical purposes. Neither "lime," nor "carbonic acid," ever exists in marl—but a third substance formed of these two. If it were proper to name the separate constituent parts of a body, though never found except in combination, instead of the compound itself—then the author ought to have gone back a step farther, and stated these ingredients in the more remote elements, which constitute by their combination the lime and carbonic acid—dividing the first into *calcium* and *oxygen*, and the latter into *carbon* and *oxygen*. Yet we have known nearly a dozen different men and boys, who, without knowing the meaning of either of these terms, or even in what proportions carbonic acid and lime combined to form the carbonate of lime, could analyze marl with so much ease and correctness, that their results might be received with confidence. To separate correctly and ascertain the proportion of the calcareous ingredients of marl, may be learned and practised more easily than either of the household jobs of making a pot of soap, or a loaf of good bread—both of which are also chemical operations. The process is so mechanical, that it has occurred to our mind that the business of *marl proving* was one that might be carried on advantageously for the undertaker, and still more so for his employers or customers. Any intelligent youth, or female, might learn the processes in a few days, and then, if receiving sufficient employment, might analyze any specimens of marl furnished, for a very small compensation, and yet make good profits. The indolence or negligence of most marling farmers will always prevent their performing this necessary operation for themselves—and perhaps many who even understand the process, would prefer to pay 50 or 100 cents for each trial, to any competent person who would undertake the trouble.

But besides the making a mysterious and difficult business of a very simple and easily practicable operation, there are strong objections to the results of the author, even though obtained by so much superfluous skill and care. In the general remarks on the table, he says—

"The owners of the marl-beds from which these specimens were taken, are informed that the operations for analysis have been conducted on small quantities of the marl (generally the friable portions of it) the larger fragments of fossil shells having been cast aside; so that when applied in considerable quantities, these shells will by their disintegration, furnish an additional proportion of carbonate of lime and consequently enhance the value of the marl. It was deemed more advantageous to operate in the manner just indicated, in order to ascertain more accurately the respective proportions of the different ingredients."

It is very true that this disintegration will go on, and consequently enhance the value of the marl; and the practical marler knows that this process generally proceeds so rapidly, that to exclude all the larger fragments of shells from the analysis, is equivalent to destroying its pretensions to accuracy. There are certainly objections to including the most indestructible shells, without any separate notice, and counting all the parts as alike: but of the two, this mode would be more correct, agriculturally as well as chemically, than the one adopted. The farmer knows, or will soon learn, that the fossil oyster, and scallop shells are very slow in coming to pieces, and that therefore they are of but little value. But the white shells seem to be dissolved by combining with the soil, (if in a soil much needing calcareous manure,) and however solid when applied, will mostly disappear in a few years.

So much as to the analysis itself. But even if that process is perfectly accurate, and altogether unobjectionable as to each particular specimen of marl, the manner of selecting the specimens may have been such that the results of analysis may be of little value for showing the average strength of even one body of marl—and of far less, as evidences of the average quality of the marls of a neighborhood generally. The geologist does not always say how his specimens were obtained: but as it is almost impossible that he could have selected many himself, it may be inferred that most of the specimens were selected by other persons. Then the chemist is not responsible for the specimens showing any thing like fair averages of quality, and there are several reasons for believing that without a proper and careful selection of specimens, the most correct analysis is of no value, except as showing the constitution of the particular specimen examined—or (in some rare cases,) some new ingredient, (as green sand, for example,) and of course suggesting the probability of the presence of that ingredient through an extensive region. When the author describes the marls of a particular farm, and even generally of a neighborhood, he refers, in most cases, (as is seen in the foregoing extracts,) to one or two specimens only, in his table, to show the quality. Now we have rarely, if ever, seen a single bed of marl dug into eight feet, that did not present different layers of various degrees of strength in shelly matter. Sometimes one layer lying within a foot of another, above or below, is of double the strength—and sometimes a bed which in part contains 60 or 70 per cent. of carbonate of lime, will in another part be below 20, and not worth using. The diversity is greater in different beds on the same farm, and still greater through a neighborhood of some extent. Of course, one or two specimens, and especially without particularly describing the precise locality, and from what part of the bed each was taken, could give but little if any information, even if selected by the geologist himself. But if selected by othes—either ignorance, or carelessness, or self-interest, or a desire of a proprietor to show better marl than others, might cause an exhibition of a very rich specimen from a bed generally much poorer. For these several reasons, but little importance can be attached to the results presented in the table of calcareous marls—and so far as our latter objections apply, the fault is not the author's, (nor the proprietor's) but of the plan fixed by law under which he acted, and by which he was bound to be governed. In making it the duty of the geological surveyor to analyze the various specimens of marl, soil, &c. sent him by any proprietors, he was left no choice but to perform a vast deal of arduous, yet mechanical, and often useless labor, of which the results must be necessarily mostly mere rubbish. The worker of a marl pit who desires to know its average strength, should take specimens carefully and fairly selected at various depths, and certainly at every change of appearance. A single digging may sometimes require a dozen trials, if great accuracy is deemed necessary. But after this is done, the same bed might be worked for years, without showing a variation worth notice, from the same general character, or average strength. And indeed, the practised eye may easily know the same bed though found at some miles distance, and may be satisfied with the analyses made from the earlier known locality.

The observations made by the author through the report are as often agricultural as geological, and on that account might be supposed to promise the more value, to the farmers of Maryland. But the duty was of course confided to one chosen as a geologist and chemist, and not as an agriculturist—and however desirable the union of all three branches of knowledge may be in the individual appointed to make a geological survey, it is not to be looked for. But it may perhaps deserve consideration whether the general and most important objects of such a survey would not be advanced by the aid of an intelligent agriculturist to the more scientific labors of the geologist, and which should be confined to drawing these practical deductions for which the man of science is rarely qualified. If one of the many enlightened farmers of the Eastern Shore of Maryland had for this purpose been associated with the geologist the latter might have been saved much of the trouble of making observations of matters of practical agriculture, and that branch of the subject could have been made far more full, correct and useful.

It seems to be a remarkable deficiency in the report, that though it was made by the law part of the surveyor's duty "to analyze and ascertain the qualities and properties of all specimens of mineral substances, *or soil*, left at his office or residence, for that purpose by any citizen of the state, and taken from any portion of the territory of the state"—that not a single analysis of any *soil* is given. Nor is there any indication of the constituent parts, other than such as the eye of an unlearned observer might direct, except that it is incidentally and slightly observed (p. 21) that the soil lying over the marl "is never found to contain calcareous particles." If the author meant to convey (as is maintained generally in the Essay on on Calcareous Manures—) that the soil is generally, if not entirely destitute of any portion of carbonate of lime—it would have been gratifying if he had been more particular, and had commented on the remarkable difference in that respect between the soils of that region, and the usual constitution of most of those soils in Europe of which any knowledge is to be gained from books.

In furnishing directions for working marl pits, and applying marl, and making observations on the practical effects of the manure, the author quotes largely from the Essay on Calcareous Manures, to which work due credit is given. We will pass by this part of the report, and proceed to the account of the beds of marl, and the green sand formation of the Western Shore of Maryland.

"*Principal localities of the shell-marl deposites on the Potomac, their constitution, relative value, and use.*

"As the use of marl has scarcely been at all resorted to on the Western Shore of Maryland—although from its quality as it there occurs, and the condition of the soil by which it is overlaid, its application would be of the greatest benefit—it is deemed a matter of infinite importance to indicate, as precisely as the extent of the examinations so far made will permit, the situations in which it has been discovered, or where it is likely to be found by proper research.

"A very extensive and very accessible deposite of marl occurs near Piscatawa, on the north side of the creek. The bed is overlaid by a thick crust of indurated shells and sand, that can, however, be easily removed, and beneath which is the friable marl in an excellent condition for immediate use. The analysis of this marl is given at No. 42 of the table. No. 43 indicates the constitution of a marl occurring under similar circumstances with the preceding, at Upper Marlborough. These two localities are to be considered in fact, only the most prominent points of a great fossil deposite, extending from Fort Washington to the west branch of the Patuxent. This deposite will, no doubt, be soon discovered on intermediate spots, from which it can be extracted with equal facilities, so as more generally to diffuse the benefits which its application to the soil must inevitably produce. The situations that may be indicated, as those where it is most likely to make its appearance, are along the small branches that make into the Piscatawa, on either side. The village of Piscatawa is based on a bed of marl, and in its vicinity, at a place called the marl bottom, the material has been employed with the usual success. We are indebted to Dominick Young, Esq. for this perhaps solitary, experiment made on the Western Shore of Maryland, on the good effects of marl. Much regret is felt, that, owing to the absence of that gentleman from his plantation, a full account of the result of his experience was not obtained. It is desirable indeed to ascertain the operation of marl on differently constituted soils, and a knowledge of their natural fertility or susceptibilities—never better discovered than by agricultural experiments—is essential, in order to arrive at safe conclusions. The directions given in a former part of this report as to the manner of employing the marl on the Eastern Shore, will no doubt apply here: at all events it will be perfectly safe to follow them on wheat and corn lands; but we possess, as yet, no information as to its effects on tobacco lands. Reasoning from analogy, no mischief can be apprehended from the use of marl on these as on other lands; but in order to direct its proper application, as to *quantity* especially, we should be aided by at least a few positive results. It is hoped that the efforts made to interest the planters of this part of Prince George's county in the subject, will soon supply this desideratum.

'Charles county, also, is abundantly supplied with marl. A great deposite of fossil shells, similar in character to that at Fort Washington, occurs between Pye's landing and Indian-head, stretching across Cornwallis neck to the Mattawoman. A partial application of the material from this locality, is said to have been made to the soil above it by the former proprietor of the landing, and report states that it proved very serviceable; yet it was discontinued. We have the assurance from the present owner, Mr. John Pye, that it shall not be any longer neglected. The banks of the Potomac, from what are termed the blue banks along Wade's bay to Smith's point, exhibit likewise one continuous deposite of fossil shells from thirty to forty feet above tide. Nos. 46 and 47 indicate the analyses of these marls.

South of the Mattawoman, and embracing the large tract of land between it and Port Tobacco river, the diluvial formation composed of gravel, sand and clay, having a depth of from one hundred to one hundred and fifty feet, rests upon a great bed of *blue marl*, possessing very remarkable characters. Subjected to analysis, it proves not to be rich in calcareous particles, but it frequently contains *potash* as one of its constituents, by which it becomes assimilated to the green marl, so called, of New Jersey and Virginia, known to possess very fertilizing properties, although frequently without a trace of lime; as was ascertained by Professor Rogers of William and Mary college. The analyses of these marls are given at Nos. 48 to 53 of the table. It may be well to remark, that the parcels submitted to analysis were obtained under quite unfavorable circumstances, being mostly the superior water-worn portions of beds thus uncovered at the bottom of ravines, and made known during our examinations of the past year. A transient inspection of these deposites led to suspect that at a greater depth, their contents would be found more valuable—inasmuch as they might be expected to yield a larger quantity of fossil shells, which by their disintegration would increase the proportion of calcareous particles. This conjecture has been verified by the subsequent researches of Capt. Walter D. Miller on Ward's branch in Nanjemoy. An immense agricultural resource is thus shown to be at hand for the benefit of this portion of the state, of which the intelligent planters of this district, in Charles county, will certainly lose no time in taking advantage. The places at which it has been so far discovered, are the heads of the small branches making into the south side of the Mattawoman, on the plantations of William Dulany, Esq. and Mr. John Pye; at the heads of similar branches emptying into the Nanjemoy, on the estate of Capt. Alexander Gray; and at Port Tobacco It may confidently be looked for at the head of all the deep ravines that furrow the highlands, to discharge their waters into the Potomac or its creeks.

"From the nature of this *blue marl*, and the condition of the soil belonging to the hilly lands in this section of Charles county—deprived in a great measure, by washing, of their natural soil—it is believed that small applications—say of ten loads, or one hundred bushels to the acre, aided by a few loads of stable manure, and repeated to a given extent at intervals of four or five years in proportion to the progress of improvement in the soil—would be very profitable. Such soils, moreover, as are apt to wash, will by this operation have their texture greatly improved, and will be found much less liable to run into gullies. An important observation related by Mr. Ruffin is that "when a field that has been injured by washing, is *marled*, within a few years after, many of the old gullies will begin to produce vegetation, and show a soil gradually forming from the dead vegetables brought there by the wind and rains, although no means should be used to aid this operation."

"The next variety of marl to be described as appertaining to Charles county, is perhaps the most valuable material of this kind which the state possesses. It has been identified, as well by its geological relations as by its chemical composition, with the green-marl of New Jersey and Virginia. This formation in Charles county, so far as it has been traced, occurs on the Potomac, between the mouth of Port Tobacco river, and the mouth of Pope's creek, constituting the high banks of the river in nearly the whole of this extent. The situations from which the material was procured for examination are, St. Thomas's Manor, at Chapel Point, and the plantations of G. Brent and R. Digges, Esqrs. Nos. 54, 55 and 56 of the table, indicate its chemical composition." p. 43 to 46.

"To give some idea of the value of this marl," the author then quotes at length from Professor Rogers' paper on the discovery of green sand in Virginia, [Farm. Reg. Vol. II. p. 129,] the statements of the remarkable effects produced on lands in New Jersey—and afterwards the description of that earth. As the entire communication is in the hands of the readers of the journal for which these remarks are designed, these quotations will be omitted here. The author then proceeds—

"The general appearance of the *green-marl* in Charles county, is pretty well represented in the name which it bears. This however. may be owing to its having been observed so far only on the dry banks. The particles of the so called green sand which it contains answer exactly the description given of them; "they are easily recognized by their want of lustre, the ease with which they may be bruised with the point of a knife, and the bright green stain which they then produce." Some of the fossils supposed to be characteristic of the formation, were also observed, especially the fossil shell called the *Gryphœa*, described as "having one valve very deep and convex, and the other flat;" and *lignite*, or carbonized wood. In two localities, at Mr. Brent's and Mr. Digges's, groupes of crystalized selenite, or gypsum, are found in the green marl; but as they occur always in the upper portions of the deposite, at a uniform elevation, and as it were in a continuous stratum, (the marl being covered with a thick coat of ferruginous sand and gravel containing iron pyrites,) it is presumed that the selenite is only an accidental constituent of the *green-marl* of these localities, produced by the decomposition of the pyrites and the action of the resulting acid upon the lime of the marl beneath. A similar formation of selenite, was described in the former report as observed in the shell-marl deposite at the mouth of St. Inigo's creek, on the St. Mary's, and this, as previously stated does not belong to the green sand formation. The phosphoric odor recognized by Professor Rogers in the marls of New Jersey, was not perceived in ours. But the foregoing points of similitude are sufficient to identify the deposites on the Potomac with the green sands of New Jersey and Virginia. On the other hand, a very useful accompaniment of the green marls of Charles county, is that of spheroidal masses of indurated marl, in shape resembling a gourd—whence they are sometimes called by the uninformed petrified gourds—and varying in size from the larger to the smaller kinds of this vegetable production. Some of these masses present when broken a nucleus apparently of the same nature as its envelope; others exhibit irregular cavities lined with an incrustation of a straw colored carbonate of lime, having the lustre of imperfectly bleached bees wax. Such is the character of these masses on the plantation of G. Brent, Esq. On St. Thomas' Manor, they more resemble irregularly shaped nodules, traversed by fissures, the sides of which are lined with selenite.

"Below Pope's creek, at Cliffton—a situation which was indicated by Col. Wm. D. Merrick, and visited in company with this gentleman and the owner, Mr. Latimer—there is an immense deposite of a *blue marl* exceedingly rich in calcareous matter, and containing moreover a notable proportion of the green sand. The analysis of this marl is given at No. 57, of the table. The bed of marl now referred to is elevated from thirty to fifty feet above high tide, and is covered by a stratum of diluvial gravel from ten to twenty feet in depth. It is decidedly one of the most important deposites of marl hitherto discovered on either shore of the Chesapeake bay. Whenever the value of its contents shall be duly appreciated it will prove the source of renewed prosperity to the adjacent country, and of wealth to its fortunate proprietor. That marl is destined to become ere long an article of barter and exchange, as lime, plaster of Paris, &c. are now, there cannot be the least doubt; and no situation is known in Maryland that possesses more advantages for its easy delivery and general distribution than Clifton. Should the public attention be called to this subject to the extent that it deserves, it is the duty of the state geologist to furnish proper directions for the best mode of extracting it. Other situations presenting the same, or not much inferior advantages, may be hereafter discovered.

"It was stated before that a stratum of *copperas earth*, was occasionally found associated with the marl of this region of country. It can be easily recognized by a greenish efflorescence which usually takes place on its surface after a very slight exposure, due to the formation of a saline substance characterized by a styptic taste, and very well known in the domestic and useful arts by the name of *green vitriol*. A stratum of this earth varying from twenty to thirty feet in depth was observed overlying the marl on the plantation of G. Brent, Esq. Care must be had not to confound this article with the green marl, which it somewhat resembles, as its application to the soil would probably prove injurious."—p. 47 to 49.

We have entire confidence in the statements and opinions of Mr. Rogers, as quoted by the author. But while admitting fully the facts of the remarkable and valuable operation of the green sand as a manure, in the cases cited, and in very many others, we more than doubt the soundness of what seems to be the deduction, that equal, (if indeed any) benefit may be expected generally on most soils of the region convenient to this earth where found in Maryland. The marl referred to above (No. 57) as promising so much value, even as an article of commerce, and stated as "*exceedingly rich* in calcareous matter, and containing moreover a notable proportion of green sand," contains, according to the table, only 13 per cent. of lime, and 11 of carbonic acid, (or 24 per cent. of carbonate of lime) and would be rated rather as poor than rich. We cannot be sure, from the manner in which the constituent parts are stated, how much of this specimen is properly *green sand:* but it cannot be large, as the potash, which forms one of its uniform constituent parts, amounts only to one per cent.

This singular earth, the green sand, offers a most interesting subject for both chemical and agricultural investigation—and one of which almost every thing is yet to be learned; and if the mode in which this manure acts, can be discovered, and its operation be secured in most cases when applied, then indeed it will prove a treasure of incalculable value. But so far, no chemist has even made even a plausible surmise of what constitutes the peculiar value of this earth, or how it acts: and we are at present persuaded that in practice it will rarely be found beneficial, unless when combined with calcareous manure, or applied to soil made calcareous previously by nature or by art. This is admitted to be an opinion, which, though founded in part on practice, needs many more experiments to confirm its truth. But if true, there can be no fair comparison of value between any certain quantities of calcareous marl and of green sand, as manures, unless the suitability of the soil for each is first ascertained. The application of one ton of green sand may in some cases add as much to the succeeding crop as 20 tons of shell-marl on another soil—and perhaps one bushel of gypsum elsewhere would be as striking in effect. But it would be a very incorrect deduction thence to estimate these several quantities of different manure as of equal value: and still more erroneous would the supposition be, if made in regard to soils, (such as we believe most in lower Maryland will prove to be,) on which neither green sand nor gypsum will show their best effects, until *after* the application of calcareous manures. According to these views, we infer that the marls of the Western Shore which are sufficiently rich in calcareous matter to be valuable on that account, and also contain a small proportion of green sand, will exhibit more effect from the latter, than even a pure green sand, without any accompaniment of calcareous matter.

Dr. Ducatel has found no trace of green sand in any of the marls east of the Chesapeake—but more or less of that substance is exhibited in all the specimens (in his tabular view,) on the western side, in Prince George's and Charles Counties. None of these are entirely destitute of carbonate of lime, as in much of the like formation in Virginia, and in New Jersey: but that ingredient is generally in small quantity, and in one (No. 54, from St. Thomas' Manor,) the proportion is only $2\frac{1}{4}$ per cent. Such earth as this certainly does not deserve the name of *marl*, if that term means a calcareous earth, or manure—and it is to be regretted that the countenance of a man of science should thus be given to this incorrect and inconvenient designation.

THE INEFFICACY OF LIMING SEED WHEAT AS A PROTECTION FROM HESSIAN FLY—TARRING SEED CORN.

To the Editor of the Farmer's Register.

I am aware that a large majority of your subscribers are as well, or better qualified than myself, to contribute to your valuable journal; this, however, shall not deter me from performing what I conceive to be my duty, and that of every farmer—being encouraged by the recollection of the poor widow's mite. If an apology should be deemed necessary for thus intruding, the only one I shall present is, that my example may prove an incentive to others, who, beholding my feeble efforts and penury, may be induced to contribute from their abundance.

But to the point. In Vol. I. page 351 of the Farmer's Register, there is an article, taken from the *Canadian Courant*, which professes to be an infallible method of destroying the Hessian fly, by soaking and liming the seed wheat. You, Mr. Editor, made some remarks upon this article, expressing your doubts both as to the remedy, and origin of the Hessian fly, and "invited the expression of every opinion sustained by well attested facts on a subject so important." Of the origin of this fly, I know nothing. As to the efficacy of the above remedy, I had little more confidence than yourself; but thought it wrong to condemn without trial, and accordingly made experiment as directed—by soaking and liming a half bushel of wheat. This I sowed upon a good piece of land, on either side of which, and upon like land, I sowed unlimed wheat. In the spring, when I discovered that the fly had commenced its depredations, it reminded me of the lime experiment; and I at once determined to test its efficacy by making an examination. In passing through some unlimed wheat, I found the fly quite numerous: when I reached the limed wheat, my sincere desire was, that the experiment should prove successful, and that not a vestige of the fly be found; but alas! Mr. Editor, how often are our fondest hopes blasted. Upon examination, I found the fly as numerous here, as elsewhere, and, I really imagined, that it was more so. When this wheat was harvested I could not discover that it possessed any superiority whatever over the other, either in quality or quantity. This experiment I have never tried but once, and do not doubt but that it has proved successful under peculiar circumstances. But from the trial I have made, I am satisfied in my own mind, and shall never attempt it again, until the remedy has been fully, fairly, and incontestably proven to be effectual.

Whilst I am writing, it will not be amiss, perhaps, to fill out the sheet; you can take it for what it is worth.

As the season for planting corn is approaching, permit me to recommend an article in the 14th Vol. 59th page of the *American Farmer*, to the perusal of your readers, upon the subject of preparing or tarring seed corn, as a means of protection against crows, hens, black birds, and all others of the feathered tribe. In case the work should not be at hand, I will give the substance of the article, which will be sufficient for any one who is disposed to try it. The process is as follows: "Take a peck of corn and pour on it hot water, (without detriment)—after standing a few minutes, draw off the water. The tar, having been warmed sufficiently to reduce it to a fluid state, is then applied to the corn in small quantities, stirring at the same time, until all the corn is thoroughly daubed with tar. Then apply plaster, ashes or lime, one of these substances, intermixed with the corn will prevent cohesion and give better thrift to the crop. A peck of corn is as large a quantity as will be found convenient to operate upon at a time. A quart of tar is sufficient for a bushel of seed. The tar however, should not be applied sparingly. No injury, to my knowledge, has ever been done to seed, by any part of this process. I have practised preparing my seed corn in this manner for more than thirty years, and can recommend it as an effectual security against all manner of fowls that have been known to disturb corn fields." It would seem perhaps, that the author of the above, was rather sanguine in his assertions; but if any statement of mine, as an anonymous writer, will have any bearing, or corroborate those assertions, I can bear testimony to most of the facts therein stated. The tarring process has been practised upon my farm for several years, and as far as it has come under my observation, I believe it to be an effectual security against the depredations of the whole feathered family. But there is another advantage from tarring corn, which is, that plaster adheres more readily, and in a much larger quantity, which is a matter of much importance in this section of country.

I wish that some of my Madison and Orange acquaintances could be prevailed upon to write for the Register, knowing that they possess much interesting and valuable information, which they willingly communicate orally, but when applied to to write, they seem to startle at the very idea; and that false sense of reserve, or a distrust in their own dormant powers, so frequently condemned, and which has been so injurious to the agricultural interest, causes them to lose sight of every other consideration. Owing, no doubt, to this cause, much valuable agricultural knowledge has been lost to posterity: its possessors choosing rather to keep it locked up in their own bosoms, and carry it unrevealed to their graves, than to communicate in writing a few plain, simple, unvarnished facts: such Mr. Editor, as are not only more convenient to the editorial fraternity, but more interesting and acceptable to the general reader. There are other matters that I intended to have noticed, but fearing that I have already trespassed too long, and that I shall run into the other extreme, of writing too much, I am therefore admonished to conclude. May success attend you in the cause of agriculture—which is the cause of our country.

CROOKED RUN.

Madison County, Va.

[We concur entirely with our correspondent in the general remarks on communications from practical men, and the strong aversion to writing which such men generally feel. There are hundreds among our readers, each of whom could tell sufficiently well in few words, of some facts, or observations, which would be useful to many other readers, and perhaps interesting to all. But in addition to the general repugnance to writing, (which this work has done what we deem its greatest service, in lessening,) thousands of such matters are kept back by those who know them, because, as they would say, if asked to give any such matter to the public, "Oh! that is quite too trifling to write about." Now, this is a great mistake, which reason alone and common sense ought to prove—but which would be proved beyond dispute to every one who would look over any dozen copies of different agricultural papers. It will be there seen that nearly all the articles copied from other publications are very short—indeed it would seem that with many editors the small size of an article formed its principal recommendation for selection and republication. We have observed that most of the very short original articles in the Farmers' Register on particular subjects, are republished in almost every agricultural paper of the country—while but few that occupy several pages are republished in any: and none that are long, however good, are favored with any thing like the extent of circulation, as many of the shortest, of very moderate claim to merit. Let any of our readers try the experiment, by sending us some practical fact or useful observation contained in half a column or less, stated in the most plain and simple manner, and also a communication of several pages drawn up with the utmost care, and in his best style—and we will pay any reasonable penalty if there are not manifest proofs exhibited afterwards that the first will have more readers, and more republications, than the last.

But though these reasons are stated as inducements for bringing forward the many short pieces which might be so readily furnished, let it not be thence inferred that we object to long ones, or that it is deemed desirable to compress any subject within smaller space than its full developement would make necessary. Such an inference, and the action under it, would be a greater error than withholding concise statements, because they cannot be presented in all the dignity of regular and extended essays. Every subject that deserves being treated at all, ought to be treated sufficiently in detail to be made clear—and to agricultural subjects more than perhaps any other kind, does this rule especially apply. That the length of a communication operates to lessen the number of its readers and to limit the extent of its circulation, is a fact which is to be lamented, but neither can nor ought to be disguised —and every writer may make good use of the knowledge of this evidence of the general carelessness or bad taste of the reading public, But if articles which require to be treated at length have fewer readers, they are at least more highly prized by those few; and thus perhaps gain as much, in the higher estimation of the few, as short articles do from a far more general, but more careless reading.]

From the Cultivator.

QUERIES AND ANSWERS IN RELATION TO SHEEP HUSBANDRY.

The five queries which are quoted below, came from an anonymous correspondent. They were forwarded to a gentleman preeminently distinguished as one of the best judges of stock, and withal an extensive breeder, who has promptly and very obligingly furnished us with the subjoined answers. *Ed. Cul.*

1. "Of what breed or stock had a beginner better compose his flock, his object being the growing of fine wool?" Pure Merino, crossed with high bred South Downs.

2. "What are the prices at which the Saxony, South Down, Cotswold, Leicester, Bakewell, or Merino ewes, can be purchased respectively, after shearing?" From a *good* flock, you cannot *select ewes*, or it would not long remain a good flock; lambs or yearlings may be selected perhaps—price very various—depending on purity of blood, and individual excellence.

3. "What breed produces wool of the greatest value?" Saxony *per pound*—Merino *per fleece.* "And what breed yields the heaviest fleeces?" The great Lincoln, or Romney Marsh sheep.

4. "What breed is most hardy and best adapted to our climate?" South Downs, *certainly.*

5. "On what lands how many sheep per acre can be profitably kept?" That depends on the breed of sheep, and quality of land, but much fewer than are generally kept.

The Saxon sheep undoubtedly produce the finest wool; but their fleece is light, seldom exceeding $2\frac{1}{4}$ lb. in weight, and is too open to resist our storms. They are feeble in constitution—require great care, are poor nurses, and their lambs are raised with difficulty. The mutton from such sheep must necessarily be of a miserable description.

I believe that in Connecticut, even the pure Saxony sheep may now be purchased at a comparatively low price, say from six dollars to four dollars a head, and perhaps lower still.

The *old fashioned pure* Merino sheep, which were imported by Col. Humphrey, and those associated with him, (but which are now almost extinct) were a much better constitution sheep, and *more* than made up by quantity for the difference in the quality of their fleece—the close, thick texture of their wool resisted our cold wet storms—their lambs were much easier raised, the ewes were better nurses, and on the whole, I am convinced they are a much more profitable sheep than the Saxony. I must, however, remark, there are several varieties of the Spanish sheep; and I would carefully avoid the "gummy"* family fleece, which however, must not be confounded with that, which, though of a dark color, contains only the grease necessary to render it impenetrable to the weather; the former being very objectionable to the manufacturer, while the latter is readily cleansed and worked.

I desire to be understood as speaking of the *pure* breeds, and not of *grade* sheep, which so universally abound in this state, for *they* have no distinctive or fixed character, but vary with their degree of consanguinity to the pure imported blood. Indeed I feel well assured that there are very few individuals of the pure unmixed blood to be found.

The earlier Merino flocks of this state, were obtained from the introduction of imported bucks, and those were purchased at great prices, which, with the native ewe, formed the ancestry of our fine wooled flocks; these had not attained nearly to the excellence of the pure Merino, in the staple of its wool—its compactness—its uniformity, or softness—when the Saxony cross was introduced, and became almost universal in a surprisingly short time—and this is the true history of almost all our fine grade sheep in this state. It is not, therefore, to these flocks that I allude, when I speak of *pure* Merino, or Saxony sheep.

As to price, I presume such Merino sheep are more costly now than the Saxony, from the fact that farmers are now aware of their error in using the Saxon cross, which has ruined the constitution of their flocks, decreased their clip of wool nearly one-half, and reduced their produce, until, with ordinary management, more than twenty-five lambs to an hundred ewes, are seldom raised. A Merino buck, of *unquestionable* purity, whose ancestry were both imported, will now sell for twenty-five and thirty dollars; the same animal, eighteen months since, might have been picked up at $8 and $10.

The Leicestershire, Bakewell, and Cotswold sheep are so crossed and mingled in this country, that the distinction is lost, excepting to the practised eye, who can find individuals in the various

* The term "gummy" is in common use with farmers, and will be understood.

flocks which partake, as it may happen, more of the characteristics of one parent or the other.—These are a long, coarse wooled sheep, possessing much beauty of form, early maturity, and are quick feeders; but they require rich lands for their pasture, and though their constitutions are good, yet their fleece is sufficiently open to admit the penetrating rains of our severe storms, and then it is, that their heavy fleeces are seen separated along the ridge of the back, thus admitting the wet directly to the skin, until the animal is chilled through. They are good nurses, and make fine lambs; their meat originally coarse and long in the grain, and white in its color, was much improved by Mr. Bakewell, and under his management, became superior to the other large, long wooled sheep. Some of the best flocks of this variety may, I believe, be found in the sheep-folds of Mr. Dunn, and Mr. Wilkinson, in Albany county, or of Mr. Adcock, Mr. Musson and Mr. Clark, in Ostego county, all of whom have given much attention to this fine variety of sheep. Average produce in wool, I should think, from five to six pounds, though individuals are found, carrying fleeces of ten and twelve pounds! Price of good lambs, I believe, from ten to fifteen dollars.

The South Downs are as yet but little known in this country, but in my opinion, are decidedly better calculated than any other, for the domestic purposes of our farmers. They are of a medium size, beautiful in their forms, large loined, broad chested, fine in the head, small boned, and fine in the fleece, which averages four pounds in the ewes; the bucks reach to seven pounds; in quality it is equal to half blood Merino, but stronger in its filament, and *entirely* impenetrable to storms of snow, sleet, or rain; they are regardless of our coldest weather, and possess hardier constitutions than any sheep I know. The wethers attain to about 28 lbs. per quarter, and are allowed to be the best mutton sheep in England, the meat being dark in color, short grained, mild in flavor, and juicy. They are excellent nurses, and quick feeders. Here again, I beg to be understood as alluding to the *pure* and *high bred* South Down; such as it is found in the sheep-folds of the great sheep masters in Sussex; not the common, unimproved animal of the Downs, weighing 14 lbs. per quarter, and carrying but 2½ of wool.

As to prices—they are best ascertained from the sources of the respective breeds, and must vary much, according to the established purity of the blood, and the excellence of the individuals; the one a much more difficult point to ascertain than the other.

For the last three years, preparative to commencing my own flock, I paid much attention to the sheep husbandry of this district; visited those who owned large flocks, and soon discovered that they were all on the decline; I corresponded with others, and found the introduction of the Saxony blood was universally followed by a decline of constitution, and all its attendant evils; excepting in one instance, where a gentleman wrote me, that he had just purchased a flock of Saxon Merinos. He assured me that in Oneida county, they were a hardy, healthy sheep—shearing on an average about three pounds of wool, and the purer the Saxon blood, the heavier was the fleece! ! This was so contrary to my own experience, having materially injured a flock of nearly two thousand grade Merinos by one single cross of the Saxony, that I still continued my plan of forming a flock from the *pure, full bred,* large Merino sheep on the one part, and from the high bred sheep of Mr. Ellman's flock of South Downs on the other. Assisted by the indefatigable perseverance, acute discrimination, and previous knowledge of a friend (whose father was concerned with Col. Humphrey in his various importations and sales of such sheep,) I collected, after 18 months search, about thirty full bred Merino sheep, pure as imported, *known* to be directly descended from those importations. Their quality of wool is as fine as perhaps any grade Saxony flock around me. The ewes will average four pounds fleeces. My South Downs I imported from the celebrated flocks of Mr. Ellman, in England, whose two year old wether sheep beat all England last Christmas, at Smithfield, and took the first prize. He was judged to weigh 32 lbs. per quarter; and I am happy to say, has been presented to me by Mr. Ellman, as a specimen of excellence, and will probably arrive in this country before long, as he was to be shipped from London the first week in this month, for New York. From Mr. Ellman, I procured six yearling ewes, and a *yearling* buck; the ewes have wintered in a yard with an *open* fence, and an open shed, closed only at the back; they lambed there from the 23d to the 28th of February, on which day the thermometer was as low as 4°. On the 1st, 2d, 3d, 4th and 5th of March, the thermometer, in the shade, was from zero to as low as 6 degrees below zero, at sunrise! and yet my lambs, young as they were, never suffered in the least from the severity of the cold; they never showed the slightest consciousness of its intensity! and are allowed by all who call to see them, to be the finest lambs they ever saw. I find a rapid demand for all I can spare from both my flocks, at liberal prices. The engagements for my South Down buck, for next season, have been filled for some months past; and two days since Mr. Musson, a Leicestershire breeder, called to see him, when I took the opportunity of requesting he would weigh him—he very obligingly did so; and his exact weight was one hundred and fifty-nine pounds and a half. I have ventured on these minutiæ in regard to the *high bred* South Downs, as these sheep are very little known in the United States; and facts are more satisfactory than opinions: and again I must insist that I do not allude to the *unimproved* breed; I do not allude to the South Downs of Cully's day, from whose writings I have seen various extracts as descriptive of the breed, nor do I include the Hampshire Downs; I confine myself to the *high bred sheep* of the present day; and if any would oppose to them the fast rooted prejudice of high breeding being inseparable from delicacy, I would refer them to the facts above stated, and ask of them a personal inspection. I would further add, that it is an acknowledged fact, that Mr. Ellman's flock turns out more lambs than ewes! averaging 750 lambs annually, for several years, from 600 ewes.

A strong advocate myself for purity of blood, and a known line of ancestry, which confers excellence by descent, still, I believe, for this country, the most valuable description of sheep may be raised by judiciously crossing the Merino and South Downs, thus uniting the fine fleece of the one with the beautiful carcass of the other, and gaining at once a constitution suited to our climate. This was done some years since, on the introduction of the Merinos into England, and was attended by the most flattering success, the flock beating every other for the combined excellence of wool and carcass. Both these breeds being fine, close wooled sheep, there is no extravagant dissimilarity, no wide contrasts to be amalgamated, and a more uniform character is easily obtained in the progeny, from which it will do to breed again. This is not the case with a cross between the long and short wooled varieties; the first cross will sometimes make a good animal, but when bred from again, the produce is uncertain, sometimes "taking back" on the long wooled parent, and sometimes on the opposite side; and when apparently combining in the fleece a united influence of the two breeds, a closer examination will show an unevenness of length and filament that ill suits the manufacturer.

R.

Maple Grove, Otsego, March 26, 1835.

For the Farmers' Register.

THE POLICY OF THE LAW OF ENCLOSURES DEFENDED.

Those who advocate the repeal of this law have fallen into an evident mistake, in supposing that the expense of fencing would be diminished by the proposed measure. A simple reference to the most approved method of stock management in some sections of our own, as well as in foreign countries, will be sufficient to satisfy any one that the successful prosecution of this branch of husbandry requires infinitely more fencing than is at present found in the greater part of eastern Virginia. The northern farmers, for instance, have, with a view to this subject, found it to their interest to divide their arable lands into a great number of small fields, comprising from ten to twenty acres each, separated from each other by permanent division fences. This arrangement is adopted in order to introduce the artificial grasses, by which their arable lands are made to answer the double purpose of grazing and tillage. (See Far. Reg. vol. I. p. 542.)

We find also that some of the most successful agriculturists in eastern Virginia have adopted a similar system. In answer to certain queries proposed by the committee of the Agricultural Society of Albemarle, Mr. John H. Craven states that he has five hundred acres under cultivation which are divided into ten fields of unequal sizes. This gentleman appears to be a successful raiser of stock of every description. His method of management as well as that of Messrs. Rogers and Meriwether may be seen by referring to the report of the committee. (See Far. Reg. vol. II. p. 226.)

The same system prevails in western Virginia, where it has been evidently copied from the northern practice. Even in those regions where live stock is the staple commodity, a similar practice obtains. We understand that hogs are raised in the western country by turning them upon clover lots and grain fields alternately. And even a portion of their corn crop in its succulent state is used in the same way. It is apparent that the use of division fences are absolutely necessary under such a system.

As it is the avowed object of the enemies of the fence law to contract the present amount of fencing (Far. Reg. vol. I. p. 396) it must of course be done by confining stock within as limited enclosures as possible. Take, for instance, an estate 400 acres of arable land, and let 100 be enclosed as a standing pasture. Upon this field all the stock necessary for the support of the estate are turned, hogs, horses, cattle and sheep. It is impossible to conceive the complicated disasters of such a scheme. In short, these standing pastures have been tried over and again, and as often abandoned, at least, as far as concerns the indiscriminate introduction of every sort of stock upon the same field. Those who use them at all, are compelled occasionally to turn a portion of their stock upon other fields, or upon the *woods range*—a resource of which they would of course be deprived upon the principles of the proposed plan.

It is true that great advantages would be obtained by making more enclosures; but it must be recollected that every additional pannel of fence is obviating the objection to the present law, in a geometrical ratio. For the sake of illustration, we will suppose that these 400 acres are in the shape of a square, or a parallelogram. The enclosure of 100 acres allotted to stock can be divided into three equal fields by running two division fences. It is easy to be perceived that by removing these and joining them again to the outside fence they can be made to enclose 100 acres more. Two additional fields of the same size will afford a sufficient number of rails to enclose 300 acres. And with seven, there will be enough to comprehend the whole 400 under one fence. And with this the objection would end. We have no doubt that such an arrangement of lots would be of vast importance in stock management. It would afford the means of introducing the culture of the artificial grasses, by which this branch of husbandry has been rendered infinitely more profitable than under the old standing pasture system. And we would remark that this is the plan recommended by the author of Arator, to whom the agriculture of Virginia is so much indebted.

The method of management is simply this: some of these fields will be sowed in small grain to be consumed by turning the stock upon it after it has ripened; or they may be harvested, and subsequently gleaned, as the individual thinks best. A similar system would be adopted with regard to the grass lots. Some will be mowed for winter consumption, others will be appropriated to grazing. And as these artificial grasses require two or three years to arrive at perfection, prudence will dictate the propriety not only of enlarging these lots, but of increasing their number as far as practicable.

We admit that where lands are devoted almost exclusively to the purposes of tillage (as they are undoubtedly with us) that fencing becomes a very heavy and unprofitable tax. But if it be the object of the agriculturist to make stock management a subject of profit, he becomes amply remunerated for any amount of fencing which may be thought necessary to promote this object. And here in fact is the secret of those rock fences which we hear of in some parts of the state—one mile of which would absolutely ruin a tobacco planter to build.

The idea that a portion of our arable lands were to remain unenclosed has always appeared to me as a very preposterous one. In those countries where the law of enclosures is not known, and where fencing is infinitely more expensive than with us, their arable lands are all carefully enclosed. Conceive for a moment, a country intercepted in every direction by public roads, filled constantly with travellers and way-faring men. It would be impossible under such circumstances, to determine whether depredation, upon the unprotected crops of the country were the result of accident or design. A drove of hogs or bullocks would fill the country with consternation and dismay. The adoption of such a system would indeed be a happy contrivance for the drover. It would save him the expense of feeding his stock from the time he passes the Virginia border until he sells out. When the supplies on one route have been exhausted he will take another: and when the highways have failed, he will take to the byways. And after he has thus consumed the whole growing crop of the state, he will then sell his meat at his own price, to the very people at whose expense it had been fattened.

It would be in vain to talk of legal restrictions and penalties: they would have no other effect than that of throwing the charges incident to such restrictions upon the shoulders of the buyer. Or of putting a final stop to the importation of live stock.

We insist that agricultural reform calls for no legislative enactment. The existing legal policy throws no obstruction whatever in the way of the individual who sincerely wishes to place his stock management upon a profitable footing. And we feel constrained to condemn all such attemps on the part of the legislature as gratuitous and uncalled for; and as oppressive in the extreme to the whole body of small farmers who constitute so large a portion of the agricultural community.

The foregoing remarks were suggested by an editorial essay on the law of enclosures, in the March number of the Register. We concur fully with the author in the impolicy and injustice of giving legislative preference to any particular branch of industry. But when he asserts that the law of enclosures is of this description we beg leave to put in our humble dissent. This law says he "and its effects exhibit a striking example of the long continued operation of the preference given by our law to the business of cattle-raising at the expense of grain raising—of a preference of grazing to tillage." We think that by referring to the circumstances which have given rise to these laws they will be found to have their origin in motives directly opposite to those ascribed by the author.

It is a fact familiar to every tobacco planter at least, that the annual *clearings* which he finds leisure to make, are utterly inadequate to his immediate demands. We speak advisedly when we assert, that according to the practice which prevails upon tobacco estates no planter expects to release any part of his arable land until it has been cultivated at least eight or ten years in succession. We will explain the "*modus operandi.*" And as the history of a single plantation will answer for that of every other, we will take, for instance, one of 500 acres, with a complement of ten hands. To each of these hands, the planter will assign 15 acres for annual cultivation; if he has a sufficient quantity of open land. The size of his whole crop will then be 150 acres; 20 of these are allotted to his tobacco, the remainder to his grain crop. All the newly cleared lands are invariably assigned to his tobacco, the first year they are cultivated: and where the lands are very good, they are tended in this crop at least three years in succession. This practice relieves the planter from the necessity of clearing land for his entire tobacco crop; which he cannot do, and tend a full crop of grain at the same time. Upon estates where a great portion of the lands have been opened, the annual "clearings" hardly ever exceed half an acre to the hand. But as our remarks have reference to rather an earlier period of operation, we will take it at a stage when they can accomplish at least a full acre each. At this rate then ten hands will be employed fifteen years in opening as much land as is allowed usually for annual cultivation. We have reduced the period to eight or ten years, because the three or four first years of settling a plantation are devoted almost entirely to the labor of clearing and fencing, as preparatory steps to the introduction of regular and systematic operations.

So then for the first ten years there is no open land to be spared for pasturage. By this time the fields that were first cleared are so much exhausted as to stand eminently in need of a little respite, if indeed they are not already irretrievably gone. In the mean time stock must be raised. During our earlier history the forest afforded an ample resource. Common interest dictated the propriety of enclosing all the arable land in order to secure the benefits of the *woods range.* And the legislature aimed at nothing more than to restrain the abuses to which the common worm fence of the country was liable.

But we will follow the history of the 500 acres farther, and see if there is any subsequent circumstance which can justify the inference of the author, that pasturage is preferred to tillage. We have seen that arable lands are consigned through necessity, to eight or ten years of constant cultivation. After this period, the three-field system is gradually introduced: viz. first year corn; second oats, or other small grain; third, rest, with pasturage: a system for a long time the boast of our agriculture, and the ultimate object to which the efforts of the planter were directed with the most anxious solicitude. It was indeed found eminently serviceable to stock raising, but it was ultimately discovered that lands deteriorated almost as fast under this system as they did from annual cultivation. Many planters, especially those upon thin lands, were therefore induced to relieve their lands altogether from the hoof, and to devote them exclusively to the purposes of tillage. And as a security against the temptation to pasturage whilst cross fences existed, they were removed, and the rails appropriated to strengthening the outward enclosure. A number of planters however still persist in the three-field system. Others again have established standing pastures. But under every system yet adopted in the tobacco region, there is some radical defect which compels the planter to resort to the importation of live stock to supply deficiencies. This is a succinct but true history of agricultural operations, wherever at least the tobacco culture has been introduced. And we discover in every circumstance connected with the subject a palpable preference of tillage to pasturage.

But there is another circumstance which goes most forcibly to strengthen this conclusion. Wherever lands are cheap, and agricultural products high, the people are disposed from principles of obvious economy to apply their labor almost exclusively to tillage. The enormous sums which the planters once received for their tobacco crops did for a time justify the neglect of every other subject of husbandry. It was indeed ripping up the goose for the golden eggs, but it was with a success the reverse of that which happened to the man in the fable. We may mourn as much as we please over our impoverished inheritance, but had our ancestors been so prudent as to have saved even a tithe of what they made by this land destroying system, we should have little cause to shed tears over their steril fields. In connection with this subject, we will advert to a capital mistake into which they very generally fell. The majority of people in every country either live up to their incomes, or beyond them. But the Virginia planter who consumed annually the proceeds of his crop had the misfortune to mistake a part of his capital for his legitimate income. But to such however, there were innumerable exceptions. Wherever the planter was actuated by prudent foresight, or love of money, his descendants have had no occasion to complain of barren fields or empty coffers. Indeed the wealthiest planters have invariably been those who have sacrificed every thing for tobacco, and left ruin and desolation in their rear.

It is true that the author speaks of the preference of grazing to tillage as a legal one. But he leaves us altogether in the dark whether he considers it as the joint voice of the people expressed through their representatives—or whether like the "Mesta" of Spain it has been the result of a spirit of monopoly and arbitrary legislation. The examples however with which he has thought proper to illustrate the subject, leave us to infer that he looks upon the law of enclosures in the light of the arbitrary edicts of a Spanish monarch.

In Great Britain and Spain as well as in all other European countries, the people are found divided into a great many powerful interests. And according as one or the other of these interests acquire the ascendancy in the national councils, the opposite one must suffer the effects of a selfish policy. But in Virginia we know no such distinctions. We combine in one character that of farmer, grazier, planter and manufacturer. And how the legislature could separate the grazing interest from the planting, we are unable to discover. The members of the Virginia legislature are chosen almost entirely by the agricultural interest. It is not reasonable to suppose that a body so constituted would have persisted in a system of local policy which daily experience proved to be inadequate to the object proposed.

Nor can the law of enclosures be regarded as an attempt on the part of the legislature to direct a portion of the labor of the state into a channel which would obviate the necessity of importing live stock—because this law had its origin at a period many years anterior to the establishment of the western states, to whom we now look for supplies of this article of consumption.

FENCEMORE.

REMARKS.

It is not the usage of this journal to bring forward in appended comments, editorial opinions, in opposition to any of different character maintained by correspondents—and though a more frequent resort to such comments has been more than once called for, it is still deemed most proper to leave every contributor free to speak, and every reader to judge for himself, of the various opinions and questionable points discussed. Whenever we have expressed objections to particular opinions, we hope that there appeared good cause for the exception, and that there was nothing in the remarks either disrespectful, or annoying to the particular correspondent. The adoption of a different course (although sanctioned by very general usage) gives an advantage to an editor, in controversy, to which he has no just claim: and still greater is this advantage made, when (as is also very common) a correspondent's argument is answered, or opposed, in *preliminary* editorial remarks.

Under the guidance of these general views, we should have submitted to the public the foregoing communication, without any accompaniment of our opposite opinions, and should have been the more inclined to pay that silent respect in this case, not only because the author well deserves respect, but also, because it is the first argument offered here in support of his side of the question, and therefore he is especially entitled to a clear field and "fair play." But as the writer has directed his strictures particularly to an editorial article, proper respect for him requires that we should depart from our usual course. Still it is not intended to discuss the general question.

There would be but little difference between our opinions as to the propriety of preserving the general principle of the law of enclosures in every such region as our correspondent describes, and which agrees very nearly with the general condition of Virginia in early times. No opponent of the law has objected to its early operation, nor to its continuance for any length of time that the same general state of things may continue in existence. The admission of the former good policy of the law was distinctly stated in one of the earliest arguments on this subject in Vol. 1. p. 396, signed "*Suum Cuique*," and such we presume are the views of all. This removes all ground of controversy as to any region just emerging from the forest state; and therefore no farther observations on this head are needed.

But even for the cleared and impoverished portions of Virginia, (embracing, with some exceptions, most of the middle and low country,) our correspondent thinks the change of principle in the law would be improper, and that even if made, more fencing would be required by good stock husbandry than is now maintained. This part of the question we are in no manner required to discuss—and therefore shall pass it by, except to notice one or two mistakes, or omissions, which serve as part of the grounds from which our correspondent's conclusions are deduced.

It is readily admitted that a very high state of culture combined with grazing, and on very rich lands, requires, for its *perfection*, numerous and good enclosures. This is one of the last steps in agricultural improvement—agreeing, in results, (from our then peculiar circumstances,) with the earliest and rudest state of tillage in Virginia. But to arrive at this *perfect condition*, embracing enclosures of every field, it is necessary that the durable materials for fencing should be sufficiently cheap—that the landmarks on which to build walls, or plant live hedges, should not be changed in every generation, or oftener—and above all, that the profits derived from grazing should be sufficient to compensate amply the additional expense of enclosures. None of these circumstances exist in our naked and poor country—and the whole rent of the country, taking rich and poor land together, would not pay for keeping it enclosed in 20 acre lots, as may be good policy in England, and even in some parts of the northern states. But as to the latter, (at least so far as we are informed,) it should be remembered that hogs are not permitted to range at large—and the fences may therefore be made at half the cost. A fence of three rails at most, in mortised posts, is ample protection against cattle—and fewer will serve with a ditch and bank. If hogs were thus confined in Virginia, half the oppression of the present law would be at once removed—and besides gaining that benefit, there would be more hogs raised in consequence of this restraint. We even suspect that our correspondent and his neighbors, abundantly as they are supplied with woods' range, would make more pork, and have less need to rely on the supplies of meat from western drovers, which he seems to admit to be now required.

But between the forest state of a young country, and the highest state of improvement of an old one, there is an immense middle ground, in which enclosures of every field, and even of every distinct property, cannot be profitably kept up—and therefore, in most countries, are wisely dispensed with. That is, the owners are secured against trespasses, and therefore are free to enclose, or not, as they please. Most of the arable land on the continent of Europe is still in this unenclosed state—and almost all of that which is not more productive than the average of eastern Virginia. Even much of the richest and best cultivated land is unenclosed, because divided into such small shares that a fence around each would be too heavy an expense to be borne. And though we will not here argue the question as to the superior share of benefit which the small or the large landholders enjoy in the law of enclosures, we will observe, that so long as that law may exist, it will be impossible for land to be held in Virginia in very small shares. The law is perpetually operating to starve out, deprive of their little freeholds, and to banish from Virginia, the valuable class of small farmers whom it is averred the system protects. It is as much the operation of the fence law to accumulate many small tracts in few hands, as it is of the law of descents (however beneficial this may be in general,) to divide these accumulations: and from the frequent changes caused by the two opposite operations, dividing landmarks, (whether between large or small farms,) cannot be expected to remain long enough to mature a live fence on, or to permit a clear profit from its being raised to be derived.

As applicable to this branch of the subject, we will take the liberty of copying some sentences of a private letter written last winter by a very intelligent gentleman, than whom, no individual would be deemed better authority—and who, in addition, is a resident cultivator of the tobacco region of Virginia, and where, it is believed, that the mode of tillage, habits, and other circumstances, either are, or were but recently, precisely similar to those in the neighborhood of our opponent. "You are right," says this gentleman, "in saying but little can be done in the way of improvement, till there is a change in our law of enclosures. The present law is dissected in a masterly manner in the Register, [No. 6,] and its absurdity completely exposed."———"You never said a truer thing, than that the poorer class was more interested in a change, than the more wealthy. There are hardly as many freeholds now as there were thirty years ago, and I verily believe that it is attributable to the present law. Small freeholds are amalgamated, brought under one fence and one owner."———"In my neighborhood there is thirty miles of fencing, and all to give to stock the benefit of promenading up and down a six-mile lane, where there is scarcely a blade of grass."

Having admitted fully the good design and policy of our law of enclosures, for the condition of the country when it was enacted, it will be unnecessary to disavow the intention of charging the present oppression to designedly partial, or worse than partial legislation. We spoke of the *operation* of the law, and not of the *intentions* of the legislators who enacted it. We never supposed that there was a deliberate design to sacrifice, or even to impair, the interests of tillage for the benefit of the interests of grazing, as a matter of general policy. But this effect is not the less produced because of its not having been intended—though (as formerly stated) without even the poor gain of benefiting the favored interest.

But however much we may differ from our esteemed correspondent on this question, we are pleased that he has come forward to maintain his opinions. It is proper that every question affecting the interests of agriculture should be fairly discussed in this journal—and none of its readers ought to object to a full expression of any honest opinion, however opposed to their own conviction.

From the Petersburg Intelligencer.

COTTON SEED OIL.

The Mayor and City Council of New Orleans have resolved to light the city with cotton seed oil. The Baltimore Patriot remarks "that the extensive experiment that is about to be made of the utility of this oil in New Orleans, will test its value, and if it should be found to possess the advantages ascribed to it, over the oil now in common use, it will, no doubt, enter largely into the consumption of every family, an prove an immense source of profit to the cotton growing portion of our country. It will in fact, be an addition, to the full amount of the oil, to their wealth, the cotton seed being now almost a useless article."

From the New England Farmer.

IMPORTANT FACTS TO BE OBSERVED IN REARING STOCK.

Mr. Editor—I have never seen in your work an account of M. Giron's experiments, which have brought forward some new and highly important laws, that regulate the form and sex of animals. A brief notice of them will be useful to all who are interested in improving stock.

M. Giron de Busareingues is an agriculturist in the south of France. His work contains two separate propositions, supported by experiments most numerous and satisfactory. The first is—that in animals of mature age and perfect developement, the influence of the sexes on the external form *crosses* in generation, the male being more like the dam, and the female progeny more like the sire. The second is—that in regard to sex itself, the influence is *direct*, the sex of the progeny corresponding with that of the parent which had the strongest constitution, and was in soundest health at the time of union.

The first of these propositions is deduced from an observation of a vast number of cases which cannot be detailed in this brief notice. After remarking then that they are sufficiently strong to convince every one of the correctness of the inference, I will proceed to state a few facts by which this second proposition is supported by M. Giron.

His first remark was, that, in his flocks and studs, those females who were at the most vigorous age, generally produced females whether united to strong or weak subjects: whilst those females that had either not attained, or had passed the prime of life, produced males when united to prime subjects, and females, when united to very old males. To ascertain whether this discovery corresponded with general observation among practical farmers, M. G. made inquiries of the neighboring agriculturists, who informed him that they had constantly remarked that when the male was young, and the female vigorous, the product of their union was female; while the contrary had as uniformly happened when the conditions were reversed.

In order to test this matter still further, M. G. announced, in 1825, to the agricultural meeting of Severac, that a part of his flock, already marked, would give him, at the next *agnelage*, more females than males. The society nominated two commissioners to ascertain the fact, and it turned out that the proportion of males to females was 1000 to 1472.

At a subsequent meeting M. G. offered to effect the production of a majority of males or females in a given flock, at the choice of the society. Two flocks were immediately furnished by members of the society.

The first flock was divided into two equal parts without reference to age or constitution. The first part being supplied with very young rams gave a product of 30 males to 76 females: the second part being supplied with strong and vigorous rams four or five years old, gave a product of 55 males to 31 females.

The second flock was also divided into two sections, but with more regard to the other conditions referred to. The first section composed of strong sheep four or five years old, was sent into rich pasturage and visited by yearling rams; it produced 15 males and 25 females. The second sections, composed of feeble sheep under four and over five years of age, was placed in dry pasturage, and received two strong rams over three years old; the result was 26 males and 14 females. In both experiments it was observed that the lambs produced by the young rams were equal in appearance to those produced by the most vigorous.

The experiments were continued on other classes of animals, birds and insects, with the same results. In the poultry yard, e. g. where the preponderance of maturity and vigor was on the part of the hen, there resulted 725 males and 1000 females: and where the male parent was most vigorous and of ripest age, there resulted 1415 males and 1000 females. Among horses his experiments were particularly clear and conclusive.

It happened to be most profitable to M. G. to have more females than males. With a view to this effect he took care, in the year 1824, to furnish his mares good pasturage, and to give none to foal who had suckled the same year or borne the year previous. "Elles ne furent presentées à l'étalon qu'apres qu'elles eurent donné des signes de chaleur." Five mares, thus prepared, produced five females; and of fifteen foals procured from 1824 to 1827 there were 13 females and two males. In accordance with the same law, it is generally true, I believe, that southern horses (particularly Arabian) produce most female colts when united to the more vigorous mares of a northern clime.

So far as M. G. extends his comments to the human race, they are not within the design of this brief communication, which is intended for the practical benefit of farmers. This benefit may be easily and plainly deducible from the above statements so far as they relate to horses and poultry. Permit me to allude to the manner in which advantage may be taken of *both propositions* in rearing *horned cattle*.

Suppose you have a cow that is a remarkable milker, and wish to procure from her a progeny with the same excellence. Now the *common* way is, to send the cow to bull, and if she has a *heifer* calf, it is raised with high expectations, and the owner is invariably disappointed. The reason of this is, as we now see, that the heifer calf partakes of the external form and peculiar properties of the bull and not of the cow. Proceeding then on the principle developed by M. G. we should do as follows: send the cow whose properties you value to a bull of the ripest age and greatest vigor. The product will be a *bull-calf* having the form and inherent properties of the mother, so far modified in their developements as the difference of sex required, but still inherently the same. This bull-calf should be carefully reared, and his female progeny will exhibit the form and properties of *his dam.*

So also if you have a bull of huge size, fine form, great strength, and other excellences, it will be in vain to expect similar form and properties in his immediate male progeny. But his heifer-calves will inherit his properties, and transmit them to their male progeny. Thus must we be content to pass through one generation, and we shall probably be well rewarded for our patience and perseverance.

It is scarcely necessary to add that such patience is not necessary in rearing horses. If you wish to procure a colt of form and properties of a fine mare, send her to a vigorous horse, and the result will probably be a male, possessing the properties and form of the dam. On the other hand, if you wish a colt resembling a celebrated stud horse, you must send such a mare (either old or very young) as will be most likely to have, from this union, a female foal, for it is in this crossing of sexes we get the external form and properties we desire.

In conclusion allow me to express the opinion that the incredulity that exists among farmers about the possibility of propagating the qualities of animals, may arise from their want of knowledge of these laws. "I don't believe in your breeds of horses," says Farmer A. "There's my neighbor B. has as fine an animal as ever stepped, that came of his old black mare that's not worth a pin." Now if farmer A. had known as much as I wish to teach him by this paper, the fact he stated would not have led him to his skeptical conclusion. If the fine young animal was a female, it matters little what were the qualities of the "old black mare," the foal partook of the form and qualities of the sire, and so on.

Yours &c.

B. C.

From the Cultivator.

DRYING GREEN CORN FOR WINTER USE.

Several methods of drying unripe corn for winter use are recommended and may be practised with advantage. Probably the worst of these is the common one of boiling, and afterwards cutting the grain from the cob. The corn is not only deprived of much of its sweetness and flavor by the boiling, but the best, though not the largest part of the kernel, the corculum, or as it is called by the farmers, chit, is left on the cob. A far better plan is that adopted by the Indians of Lake Michigan, who roast corn in a sand bath heated by a fire which they make on a bed of soft sand, into which the ears are plunged. After being roasted in this way, it is removed from the cob and kept in sacks for winter use.

A neater and still better method is, to put the ears of green corn into a baker, or oven of any kind, and roast them about as much as you would do for immediate use. The corn is then shelled, and spread to dry for a few days, either in the open air or a dry room; and may be kept for years. When thoroughly boiled (for at least 12 hours) it is as tender and soft as green corn, to which in flavor it is in no way inferior, and constitutes a most admirable ingredient in soups, or if eaten by itself is one of the most delicious and wholesome dishes that can possibly be prepared.

EDWIN JAMES.

From the Boston Transcript.

TRANSPLANTING A LARGE TREE.

The jingo tree which grew on the estate of the late Gardner Greene, and of which we spoke the other day, has been safely removed to the common, where it is to be planted. It is probably the largest tree ever transplanted in this vicinity, being 40 feet high, and the circumference, at 3½ feet from the ground, four feet four inches. The labor of transplanting it was undertaken by Mr. Sheridan, formerly gardener on the estate. The earth was carefully removed from the roots and the tree lifted by shears and tackle from the ground, sufficiently high to pass under it a low wheeled drag. The roots were then carefully covered with matting, and the tree lowered upon the drag, on which it was easily supported in an upright position, being kept from falling by ropes attached to the top and held by men who walked along with it to its destination. Mr. Sheridan tells us that there is not the slightest doubt that it will live and flourish in its new location.

From the Genesee Farmer.

MANGEL WURTZEL OR FIELD BEET.

A few remarks on the culture of this crop, now the season has arrived for commencing it, may not be unacceptable.

The soil

Is best when a clayey loam; but any soil if ploughed deep and well manured will produce good crops, as the principal requisite is depth and fertility.

The sowing

Should be done in the early part of the present month, although it is frequently performed later. Where the ground is very moist it should be sown upon ridges; but in ordinary cases, it succeeds best when planted in drills without ridging. T. and H. Little, of Newbury, Massachusetts, who raised upwards of thirty-three tons to one acre, prepared the ground and sowed in the following manner:—after one deep ploughing, the ground was furrowed two and a half feet apart, and the manure put into the furrows, and covered with the plough; a roller was then passed on the top of the ridge thus formed, to pulverize the lumps, level the surface, and press the soil and manure together. The seed were then dibbled with the finger over the manure, about six or eight inches apart. John Hare Powel sowed his crop thus:—"the holes for the seeds were made by a wheel, containing pegs in its circumference, which penetrated the ground about an inch, leaving intervals of four inches; the rows were made two feet asunder; two capsules [or berries] were dropped in each hole; the wheel of a common barrow was then passed over them, thus compressing the earth, and leaving a slight rut for the retention of moisture."

The quantity of seed

Per acre should be about four pounds; for although this is a large allowance, the expense is small when compared with the insurance of an even crop. Great care should be taken that the seed of the common red and white beet is not mixed with it. Unless the ground be very moist, the seed, before sowing, should be soaked about 48 hours in soft water. After the plants have come up, they should be thinned to about eight inches distance from each other in the rows.

The after culture

Consists principally in a free use of the cultivator, and in keeping the land perfectly clear of weeds. Col. Powel ascribes his success in the culture of this crop, to deep and thorough ploughing; to the use of cultivators, which complete the production of fine tilth; to the destruction of weeds on their first appearance; to leaving the smallest space upon which a horse can walk between the rows; and above all, *to planting the seeds of a proper kind upon a surface which is kept perfectly flat.* Gideon B. Smith of Baltimore, in 1832, planted one-sixth of an acre which had been intended for early corn, and had been manured the previous year. The seed were sown in drills two feet asunder, and eight inches apart in the drills, and covered as corn. When the plants were up, a weeding hoe was passed over the field, and afterwards a small plough run through it twice, clearing out the weeds with a hoe. This was all the cultivation it had; and the whole labor, including the original preparation of the ground, did not exceed two full days' work for one man. The crop was upwards of seventy-five bushels; and might have been much larger, as there were many vacant places of six or eight feet length in the rows; and other places where the roots were injured by being crowded. The soil was a fair medium mould, a mixture of clay, sand, and vegetable matter.*

The produce per acre,

Under ordinary culture, may be estimated at from six hundred to a thousand bushels. Where however the ground is ploughed very deep, well manured, and well cultivated, much larger crops have been obtained, of which a few instances are here given.

Gideon Foster, of Charleston, Middlesex county, Massachusetts, raised forty-three tons to the acre.

The premium crop of Tristram and Henry Little of Newbury, Mass., was 33 tons, 10 cwt. and 14 lbs. to an acre, or *more than fourteen hundred bushels.*

Col. Powel enclosed certificates to the president of the Pennsylvania Agricultural Society, showing that *sixteen hundred and thirty-four bushels* of mangel wurtzel, weighing seventy-eight thousand four hundred and forty-eight pounds, were produced upon an acre and fourteen perches; and a part of the same field containing thirteen contiguous rows, produced at the rate of *two thousand and sixty-five bushels per acre,* weighing 44 tons, five cwt. and 27 lbs.

Henry Thompson of Baltimore, raised in 1833, on less than one-eleventh of an acre, five tons, 14 cwt. and three qrs., or at the rate of about *sixty tons to the acre.*

In good land, single roots of the mangel wurtzel often weigh nine or ten pounds, and sometimes even *fourteen or fifteen pounds each;* and J. A. Kenrick of Newtown, Mass., raised in 1833, a single root weighing no less than *thirty-six pounds.*†

These products are enough to show what may yet be done in the cultivation of this crop, and present strong encouragement for the enterprize and experiment of farmers of western New York, where it has hitherto received comparatively but little attention.

* Amer. Far. vol. XV. p. 25.

† New England Farmer.

Uses.

This root is admirably adapted for feeding nearly all domestic animals. It is the best of known food for store swine; and swine fatten upon it, yielding firm pork of good flavor, when fed to them raw, equally well as upon boiled potatoes, by which the fuel and labor of boiling is saved. Col. Powel says, "my neat cattle prefer mangel wurtzel to any other root which I have offered to them. I have found its effects in producing large secretions of *good* milk, very great. * * * Its application as food for sheep is not the least important of its uses. Ewes yean usually at the season when grass cannot be supplied. The health of themselves and the thrift of their lambs, essentially depend upon succulent food being had. I am inclined to think that no small portion of the success which English breeders have met, is to be ascribed to the large stores of roots, which they always have at command."

In autumn, when the quantity of milk from cows often diminishes greatly, it may be restored by cutting the leaves of this plant and feeding them. In some instances the quantity has been doubled by this means. The leaves soon grow again, and may be cut every fortnight.* Cows fed twice a day in winter, upon 20 pounds of the roots at a time, together with four or five pounds of hay or chopped straw, will, it is asserted, give as much milk as in summer.

In some instances when fed to cattle and sheep, this root is said to have produced *scouring.* This may be owing either to the soil adhering to the roots when eaten, or to the sudden commencement of feeding on them exclusively, instead of their being mixed with a proper proportion of dry food, such as hay, meal, or chopped straw.

This crop has several important advantages in its cultivation. It is little affected by changes of the weather; suffers little from drought; thrives in most soils; is not attacked by any insect; and prepares the ground well for succeeding crops. The roots may be kept sound and fresh for eight or ten months.

Farmers who value their land, would find it greatly to their interest to direct their attention more to the cultivation of this crop. It has been found that two tons of mangel wurtzel are equal to one ton of hay for feeding milch cows; and that three tons are equal to one of hay for feeding cattle in general. Any one may readily calculate from this, how much greater a number of cattle may be supported by this means, from a given quantity of land, than by the usual mode of feeding them exclusively on grass and hay. Supposing for instance that thirty tons of mangel wurtzel are the average product per acre, then we shall have an amount from one acre alone equal to from ten to fifteen tons of hay. Now if a method should be devised for raising this amount of hay from an acre, it would excite universal attention and inquiry; but this crop, although possessing advantages not less important, is almost entirely neglected.

* It is probable however that this production of new leaves is in a greater or less degree at the expense of the root, although very large crops have been raised where this course has been pursued.

From the Journal of the Franklin Institute.

DETECTION OF ADULTERATIONS IN FLOUR.

M. Dubuc, senior, of Rouen, has applied himself with success to the detection of farinaceous mixtures in wheaten flour. The principal substances with which flour is adulterated are potato starch, a fecula; beans, barley, chalk, plaster of Paris, &c. An extract from his memoir is published in the last Bulletin of the Society of Encouragement, from which the following is taken.

There are two methods of detecting adulterated flour, mechanical and chemical. In France the adulteration is principally with potato starch, as it renders the bread whiter and heavier. If there be more than ten per cent. of potato starch, it may be detected by the naked eye, or with the aid of a magnifying glass; the fecula is whiter, the particles are angular, and reflect the rays of light, like minute crystals. To render the discovery more easy, M. Dubuc dries the suspected flour in a sand bath, at 100° to 110° of Fahrenheit; and then, with a good magnifying glass, so small an adulteration as five per cent. may easily be detected.

But if the miller has been cunning enough to grind the potato starch with the wheat, other means of detection must be had recourse to.

The first is, from the great difference between the specific gravity of wheat flour and potato starch.

The second is, that flour contains a certain per centage of *gluten*, and the starch does not contain an atom of gluten.

First method.—A vessel that will contain one pound of flour, gently pressed down, will contain a pound and a half of fecula, from these data the relative portions of flour and fecula, in any parcel of flour, may be easily ascertained very near the truth.

Second method.—The best flour contains about twenty per cent. of gluten, and, as we have stated, the starch not an atom.

Experiment.—Take five ounces of pure wheat flour, and two ounces and a half of warm water; mix and work it well for about ten minutes; the paste will be firm and elastic. Let a little warm water fall continually upon it, while you continue to knead it; by this means, all the starch and saccharine mucilage will be extracted. The operation is finished when the water flowing from it ceases to be white; what remains is gluten, the weight of which will be about one ounce. If the flour be adulterated, the paste will be more liquid, less cohesive, and less elastic, and an intelligent baker will soon be able to discover to what extent the flour has been adulterated, from the appearance of the paste, &c.

Such are the mechanical means that may be employed with success.

Employment of chemical agents to discover frauds in flour.—It will be well to bear in mind, that wheat flour is an animalized azotic matter, (*matiere animalise azotée*,) and that, on the contrary, fecula, or the starch extracted, pure from cereals, is entirely of a vegetable nature: from this difference results the varied effects of the re-agents employed.

The three chemical tests which have been found best for general use, are nitric and muriatic acid, and the liquid nitrate of mercury, (*deuto nitrate.*) Their chemical effects on flour and fecula are as follows:—

1. Nitric acid has the property of coloring wheat flour of a fine orange yellow, whereas it neither affects the color of fecula nor starch.

2. Pure muriatic acid colors good wheat flour of a deep violet, but dissolves fecula and starch, and forms with it a light, colorless, viscous fluid, decomposable by alkalies.

Experiments with nitric acid of 40°.—Take 100 grains of pure wheat flour, pour on it 100 grains of nitric acid, (aqua fortis,) in a small earthen or China cup, stirring it with a glass tube, it will heat a little, and in a few hours it will change color from yellow to a fine orange color.

Take 100 grains of fecula, and pour on it 100 grains of nitric acid; heat it in every respect the same as above, but no caloric will be evolved, and the mixture will not change color.

Take of flour 80 grains, and of fecula 20 grains, and of acid 100 grains; mix well; the color will now be much paler, and of a light citron color. Take 50 grains of flour, and 50 grains of fecula, and 100 grains of acid; mix well; the color is now much paler than before, so that, with a little practice, the quantity of fecula may be detected by the greater or less intensity of colors.

Experiments with muriatic acid of 21° *of strength.*—Take of wheat flour and acid, each 100 grains; mix well; the color will become at first red, then violet, and finish by becoming of a beautiful indigo color. This operation is accelerated if a gentle heat be applied.

Take 100 grains of fecula, and 100 grains of acid; the mixture is at first of the consistency of paste, and then becomes liquid; the fecula is dissolved, and the solution *colorless.*

On varying the proportions of flour and fecula, we shall soon be able to ascertain the quantity of fecula in a sample of suspected flour.

Experiment in the liquid nitrate of mercury.—Take of flour and nitrate each 100 grains; mix well with a glass tube or rod. The paste will at first be of a pale citron, then reddish, and in three hours will become a full red. The color is permanent.

Take 100 grains each of fecula and nitrate; they will not combine, nor will the color of the fecula or starch be acted upon.

By mixing flour and fecula in different proportions, and observing the colors, we may soon be able to detect the proportions in which flour is adulterated by fecula or starch.

It may also be observed, that fecula absorbs less water than flour, which affords a ready means of detection.

The adulteration with bean or pea flour may be detected by pouring boiling water upon it, which developes the peculiar smell of these two substances.

We may add, that the adulteration with chalk, or gypsum, may be detected by pouring a diluted acid on the suspected flour, as an effervescence will take place, and carbonic acid gas be disengaged.*

---

* There will be no effervescence from adding acid to gypsum (if it is pure,) and therefore this as a test for gypsum, is worthless.—Ed. Far. Reg.

From the Baltimore American.

VALUABLE MARBLE.

Beautiful statuary marble, said to be of the finest texture and of snowy whiteness, has been discovered in the neighborhood of Lynchburg. In some places it runs into the *verd antique* variety: "in some specimens of the latter variety, the prevailing color is a cheerful green, agreeably blended with clouds of white so as to give it a fine flocculent appearance. Some specimens of the white variety are highly translucent."

From the Norfolk Herald.

A SWIFT STEAMER.

The new steam boat Thomas Jefferson Capt. Henderson, left here on Monday morning at six o'clock, for Richmond, with passengers, and returned in season to leave again the next morning (yesterday) at the same hour! This is the first demonstration that has been given of the practicability of going from Norfolk to Richmond and returning on the same day. * * * * The distance between Norfolk and Richmond, by water, is computed at 150 miles, and as the Thomas Jefferson stopped six hours in the 24 which intervened between her time of leaving here on Monday and Tuesday mornings she run 300 miles in 18 hours; very nearly equal to seventeen miles an hour.

ON PUTRESCENT MANURES—J. M. G. IN REPLY TO J. B.

To the Editor of the Farmers' Register.

In looking over your April No., which reached me only a few days ago, I was sorry to perceive that your well informed and estimable correspondent J. B. had not taken my jocular remarks on certain parts of his former communication in quite as good part as I hoped he would—and as I was perfectly willing to take any he might make. To this conclusion I am led from his representing them as "much ado about nothing"—"word-catching-criticism"—"jeers and flouts," &c. But these little acidulated effusions are blended with so much laudatory remark on my character, style, &c.—that I should be a great churl indeed, if I could find in my heart to retort in a similar spirit.

It seems proper however, that I should notice a few passages in his communication wherein he appears to misunderstand some parts of my former letter, and may cause others to do so; while he gives to other parts an interpretation, of which they are not, I think, fairly susceptible. For example; although he does me full justice, in ascribing to inadvertence my using the terms "*not understood*," instead of "*misunderstood*," in my quotation of his italicised sentence; yet he labors through nearly a whole page to prove that this sentence would have been quite defensible had I not made the mistake. I readily admit there is some difference in the meaning of the two terms; but cannot, for the life of me, perceive, how it can be more proper to assert that "a fact *misunderstood* is not a truth," than to say, that "a fact *not understood* is not a truth." *The truth* of a fact can never, by possibility, depend upon either circumstance, although *its utility* certainly does depend upon its being *well* understood: not so much however, on a thorough comprehension of its cause, (for of that we may be utterly ignorant,) as on a perfect acquaintance with the various methods of applying it to use. I may therefore say of our friend's hard struggle in defence of his own term, as Swift did of the contests about the merits of the two foreign musicians—

> "Strange! all this difference should be,
> 'Twixt tweedle dum and tweedle dee!"

But if J. B. is satisfied with his share of this "word-catching-criticism," as he has been pleased to style it, I am perfectly content, so far as he and I are concerned, to take my leave forever hereafter, not only of that entire class of facts which he deems "*not truths*"—but likewise of our "raw meat and vegetable" discussion—of all our little "corn-stalk chimneys," either with or without "vent," "throat," "flue," "shaft," &c.—of "Nebuchadnezzar's grazing," and, though last not least, of J. B's. own happy parallel case of "Jonah's" sojourn in the fish's belly. I am willing to go still farther, and include among these "noli me tangere" topics, whatever else *he* may deem an affair of "much ado about nothing."

A few remarks more and I have done. J. B. has misapprehended several of my observations and opinions in regard to manures—their application—their waste, &c. So far as they are theoretical, I did not presume to offer them as of any value, but merely as speculations of which others possibly might make some profitable use. Still as I *have* advanced them, it seems proper to make them plainer if I can, where it appears that they have been either "*not* understood" or "*mis*understood." As to my facts, if J. B. or any other person can make a better use of them, than I have done, they are not only welcome to do so, but I shall rejoice at their superior success: for I have no particular ambition to be either the first discoverer or the best user of any thing.

The first of my opinions which he seems to misunderstand, is that in relation to ploughed and unploughed summer cow-pens. My belief in the former proving less productive than the latter is founded—*not on the supposition* that "the earth cannot retain" all the products of fermentation really congenial to her; but that when they are ploughed under to a depth below the ordinary range of the roots of such plants as we generally cultivate, such products of fermentation *remain there*, and consequently can do no good to the roots above their reach. These, it is now believed, by all who are best acquainted with vegetable physiology, have no other means of obtaining their proper food from the earth, but by little sponge-like substances—hence called "spongioles," at the extremities of each fibre, which food must first be so diluted with water as to come in contact with and be absorbed by these spongioles. To *this* circumstance, in my opinion, is attributable the apparent difference between the produce of ploughed and unploughed summer cow-pens. According to my supposition, *all* the products of fermentation which the earth is capable of receiving and retaining, will be retained in both cases; but from pens immediately ploughed, they will be retained too low beneath the surface for feeding the roots of the cultivated plants; whereas, from unploughed cow-pens they will be carried by rain no lower than they ought to go: the first is man's process—the second that of *nature*. As to what is usually called "the waste" of manure by fermentation, my conjecture, (for it is nothing more,) is, that the atmosphere takes up all which the earth cannot take, and restores it, after proper elaboration, by its natural conductors—rain, dew, and gaseous vapor. Could the whole which is drawn up from a particular quantity of manure, return exactly to the same spot first covered by the manure, or to the growth thereof, no waste, I think, would ever be suspected. But after assuming a gaseous form and becoming an aeriform fluid, its diffusibility is so great that it spreads over a much wider extent; some portion to be absorbed by the low plants near the surface of the earth, while the rest supplies food for the leaves of the fruit and forest trees. In this reciprocation, *nothing is wasted* in any sense, but all alternately given and restored—not exactly in equal proportions between so many given square feet of earth, and an equal volume of square or cubic feet of atmosphere; but the earth, as a whole, receives back the whole of every thing which the atmosphere draws from her, and which, through her, is designed as food for her vegetable productions. These remarks are here offered as explanatory of those in my former letter, which J. B. seems to have misunderstood: but *here*, as *there* I offer them merely as conjectures.

Another of my opinions which he has evidently misconceived, and from which he, of course, draws an unsustainable inference, is in relation to the restorative power of nature in fertilizing by means of leaves and other putrescent vegetable matter, worn out lands, or in making rich those which she herself had first made poor. From what I actually did say on this subject, he erroneously concludes, that "upon my theory," (as he calls it,) such "virgin wood-land" as he supposes "I may own, or am acquainted with in lower Virginia"—of which I am sorry to say there are thousands of acres—"too poor to be worth clearing or cultivating," would become as rich in about "four thousand years, as the Mississippi bottoms, or at least, as rich as it is possible for dry land to be made by putrescent manures." Now, it so happens that "*my theory*"—if he will make me the author of one, warrants no such conclusion; although—strange to say, there is a passage in his own former communication, which either does warrant it, or something that is cousin-german to it. Here it is, verbatim et literatim: "*Fortunately however, for the fertility of the earth, bountiful nature offers to the soil much more than it is deprived of by fermentation: and however great may be the losses sustained, still the gains are far greater.*" Should I not therefore have expressed myself clearly on this subject, let me make another effort to do so, lest the ingenious power of inference be brought to fix upon me theories which I have never either expressed or entertained. My belief is, that on such "virgin woodland" as J. B. describes—indeed on all virgin wood-land, the annual deposites of leaves and dead wood, do nothing more than *restore* the quantity of nutritive matter drawn from the earth by the growing trees and other plants; and that neither four thousand nor an hundred thousand years would make any of these virgin woodlands at all richer than in their original state, when first covered with wood. If this, *my* supposition, and not the theory of J. B. gives me by inference, cannot be reconciled to what he states to be "the known facts," and which I admit to be such, let it e'en travel the same road with his own dismissed sentence concerning "facts" that are not "truths."

In another place he charges me with treating "the manuring process of nature" "according to my theory" "more as a question of morals than of chemistry." If I really have done so, I must take shame to myself for being in the situation of the man who had been talking prose all his life without knowing it: for verily I cannot even conceive how a question of morals could possibly be manufactured out of such a case. But if I have unwittingly achieved this feat, I hope and trust my readers will award me due honor for it. In furtherance of this novel charge J. B. proceeds to say of himself "*I* do not treat the earth and atmosphere as "sentient and moral things;" nor do I decide by the measure of the moral wrong, or by the enormity of thus preferring against nature a "slanderous charge of grand or petty larceny" committed on the earth. *I simply refer to these facts, of the annual additions for countless ages of fertilizing matter, and that scarcely enough has been fixed in the soil to redeem it from sterility.*" As to the "*jeer*," (if he will pardon me for using his own term,) conveyed against myself in the foregoing sentence, I leave it to our readers to do what they please with it. But I beg leave to call their attention particularly to the underscored words of my quotation, and to contrast it with the sentence quoted above, from his former communication. In *that*, he positively asserts that "bountiful nature offers to the soil *much more* than it is deprived of by fermentation; and *however great may be the losses sustained, still the gains are far greater.*" In the one just given he says, "of the annual additions for countless ages of fertilizing matter," (on poor virgin woodland,) "*scarcely enough has been fixed in the soil to redeem it from sterility.*" *I* should call this a case of J. B. versus J. B., but shall leave it to *others* to designate it as they may choose.

Here ends, Mr. Editor, my attempts at explanation and acquittal. But I cannot take my leave without assuring both you and your worthy correspondent J. B. of the real esteem I feel for his talents, and character also, so far as I can infer it from his writings. I can truly affirm what I formerly said of his two communications—that I think them both interesting and valuable. Their intrinsic merit I deemed quite sufficient to secure them against being harmed, in the slightest degree, by a little jocular criticism, written in perfect good humor, and with sentiments of respect for their author. Although it is not probable that J. B. and myself shall ever again write either *at* or *to* each other, in your paper, yet it might happen. It may not therefore be amiss to say, that should it be so—as *he* seems utterly averse to every thing which even savors of a jest "in *an agricultural journal*," *I* shall endeavor to write (provided the subject be agricultural,) with as much gravity as if I were treating about the death, inhumation, and decay of human bodies, instead of the accumulation, use, and destruction of putrescent manures. A fugitive from the cave of Trophonius himself shall not surpass me in abstinence, either from laughing myself, or attempting to make others laugh: for although I myself could never perceive any good reason why a writer on almost *any* subject, should not step a little on one side, out of the beaten track, in search of a modicum of innocent mirth—seeing that there are so many more events and circumstances in the world to make weeping than laughing philosophers; yet I am perfectly willing to conform to the lawful humors of others in all matters between them and myself. Hence I will apply to our intercourse, without scruple, that favorite proverb of Sancho Panza's: "*when you are at Rome, do as they do there.*" If grave—close-to-the-point-language be the order of the day with *them*, it shall certainly be so with *me*, as far as my nature will allow me to make it so: and, like Bottom the weaver, in Shakspeare's "Midsummer Nights' Dream," I will always at least strive to be prepared, "to roar ye—an it were, as gentle as a sucking dove."

To laugh, and where few other persons perhaps, can see any good cause for it, is with me, I fear, a natural instinct; and *this*, every body knows, is hard to overcome. When therefore, provocatives fall in my way, I must either hide, or abstain from writing; otherwise the offence is almost sure to be committed, in person or in print. I call it *offence*, and I think, *properly;* for although all men enjoy the laugh of others when *with* them, yet not two probably in a thousand can even tolerate it when it is *at* them—however just and equitable this "give and take principle" certainly is. Yet with this fact constantly before me, I find myself too frequently transgressing. My only excuse—if it be any, is, that I am always perfectly willing for others to take the same liberty in this *respect* with *me* that I take with *them*. Bar ill-will, malice, and crimination of motive, and they may laugh and ridicule to their heart's content—they cannot offend me.

J. M G.

April 24*th*, 1835.

CLOSE OF THE DISCUSSION.

The foregoing communication was accompanied by a private letter from our correspondent, which stated that he did not intend to continue farther the discussion with J. B., whatever might be the reply: and as we knew that J. B. had before resolved on the like course, we thought it best that our readers should be informed on this head as well as ourselves. For this purpose, and also to guard against any improper inference being drawn as to the feelings with which either of the writers abandoned the contest, we thought it right that J. B. should have an opportunity forthwith to express to the public what we had the best reasons to know that he thought, and had before expressed on this subject, in private: and having read the foregoing, he has answered our expectations on this head in the following note.

To the Editor of the Farmers' Register.

I shall adhere strictly to my previous intention of not proceeding farther in this discussion, notwithstanding the temptation now felt to explain my meaning as to a passage of mine which your correspondent quotes, as involving contradiction. It will therefore be left to its fate. But I wish to take leave of my highly esteemed antagonist with some expression of those kind feelings which have not in the slightest degree been chilled by any thing in our controversy, and to declare to him that he is altogether mistaken in attributing any of my phrases to peevish or angry feelings having been excited. Indeed, it was really and honestly my belief, that I had avoided every thing but strictly defensive warfare—and even in that course, had not availed myself of the full extent of his invitation to make as free with him, as he had done with my piece. If then my words bore any appearance different from this opinion, it was contrary to my intention, and to the respect sincerely entertained for J. M. G. But I will say no more on this point, lest while thus offering my hand in peace, I should provoke a quarrel, like that of Sir Peter Teazle and his lady immediately after their loving reconciliation, produced by inquiring which of the two had previously given the first provocation.

Neither did I mean to express, (as J. M. G. supposes,) nor do I entertain the slightest objection to this, or any other suitable subject, being discussed in the vein of humor which J. M. G. indulges in with such good effect—and I have often joined heartily in the laugh, and not the less in the recent cases, when it was at my own expense. The objections expressed in my general remarks, were intended to be opposed to the sharpness of personal controversy—and not to the jocularity proceeding from good humor, and calculated to prevent, or allay, rather than to excite angry feelings, Long may J. M. G. indulge this vein—(of course properly directed—) and when he has—as is his usual good fortune—the "laughers on his side," I shall doubtless, be generally one of the number.

J. B.

SALE OF VIRGINIA LANDS, IN LONDON.

The following article is from the London Courier of March 26th, and is now passing through the newspapers of this country—and without comment, so far as we have yet observed.

"An important sale of freehold American lands in the state of Virginia took place on Wednesday, in the Auction Mart, which was crowded to excess with a highly respectable company. Mr. George Robins, in an able and elaborate statement, detailed the property, which was illustrated by maps and drawings. It comprehends a portion of 50,000 acres of carefully selected lands, purchased some years since under advantageous circumstances, out of 1,800,000 acres. The land is almost exempt from taxes, and the state of Virginia unencumbered by any public debt. The legislature of Virginia has recently passed an act for a rail road passing through the lands in question. The selected lands were divided into portions of various sizes from 50 to 100 and 200 acres, each of which possesses the best timber suitable for the building of houses, fences, ect. The yearly average produce of an acre of land giving from 60 to 72 bushels of Indian corn, is net in cash from £1 2s. to £1 5s.; and varying in quality from 40 to 50 bushels, from 16s. to 17s 6d. The tobacco crops are very productive. The country abounds in iron, lead, and coal mines, and Mr. Robins urged the important benefits to be derived from purchasing largely in this "the land of promise." The tiths and poor rates, were unknown in Virginia; wages were comparatively nothing. Upon a farm of 600 acres, the taxes did not exceed six shillings. The fee simple of one hundred acres of the best quality of land, which in this country would consume £5000 or £6000 might at this sale be obtained for less than £300. The lands were submitted in 91 lots—the first division, 7,265 acres in the county of Logan; the second, 2,517 acres on the waters of the Spruce Fork of Little Col River. The first parcel, containing 600 acres of land, the yearly average of taxes upon which is about 5s a year, was knocked down for 1,450 guineas. The above lot may serve as a criterion for the whole of the 47 that were submitted. The lots unsold, Mr. Robins said, were open to private contract, amounting to about five thousand acres in various farms, from 50 acres to 500 each, and will be sold by auction in London, on 15th April, in case any of them remain unsold."

It is certainly *possible*, that land as productive and valuable as that described above, and even in the county of Logan, may have been offered for sale across the Atlantic, where its worth could only be learned from the interested description of the proprietor, and the proverbial and licensed exaggerations of a land auctioneer. But it is at least highly improbable that any good land should be offered for sale under such circumstances. Land worth purchasing would naturally be offered to those who knew something of its value. The mere general statement of this transaction gives good ground to suspect that the "favorable circumstances" under which these lands were purchased, were, that they formed part of the millions of acres (real and imaginary) that have been sold by law in Virginia, for payment of taxes due thereon, according to the tax lists—and of which the greater part, if sold at a cent an acre, proved a dear bargain; but which more often, found no bidders at any price. In many cases, such delinquent lands had no existence, save on the books of the commissioners of the revenue—or if really existing, and even so well known that the purchaser will have no difficulty in finding them, consist of barren mountains, willingly perhaps forfeited by former owners, because not worth paying any tax on whatever. If this should be the result as to the buyers in this case, they will not be the first Europeans who have been thus duped, and thereby ruined—who have come to this "land of promise," believing themselves already rich, and found themselves paupers.

If there was no other objection than thus giving ground for such frauds, where our laws and usages are not known, it would be enough, for the sake of national character, to guard against the recurrence of such modes of collecting (or attempting to collect) the arrears of land taxes. It is true, that except poor foreigners, (who cannot understand that a deed executed for 5000 acres of land, by a public officer, under the commonwealth's authority, duly authenticated, and wanting in nothing of legal form, should refer to land not to be found, or held by some better right—) but few people would have been cheated by buying delinquent lands, at any price. But if there has been any benefit from the laws on this subject—any net gain to the treasury even—for all the legislation and all the complicated procedure on the subject—we are ignorant of any such results. The cost of legislation on delinquent lands, and of fees to legal officers for sales, executing and recording deeds, &c. have alone cost more than all the value of the forfeitures of land to the treasury: and where individuals have made purchases of real value, it has been often akin to fraud on the ignorant owner, and caused by the general fictitious state of these dues and sales—the vast amount of such charges, and the complication of the whole matter, —all serving to conceal the few facts among the multitude of fictions and errors.

It is not intended here to attempt the explanation of a system of measures which it is believed that very few, if any, understand, unless some public officers who have been many years engaged in executing the various laws continually superseding each other on this subject. But it may be of some use to show that it is not an intended fraud—though the result is the same—on the part of the government of Virginia, when land is sold under state authority, with every apparent security for the reality of the whole transaction, when in fact no such land can be found.

The vast accumulation, on the public lists, of land returned as indebted for tax, and finally sold by law, was not so generally caused by the tax being actually due, as by errors on the lists, which were continually added to, by the ignorance or neglect of proprietors, and the neglect, and sometimes frauds of the different officers who either listed, or collected the taxes. If A sold his land at various times, and in several parts, to B, C, and D, and then moved out of the state, each of the new purchasers had so many acres entered to himself on the tax list, without caring that A's balance was stated correctly: and if the commissioner was not very careful, and also well informed as to the transaction, when A had no balance left, and had left the state, a part, or perhaps the whole of his original tract would still stand on the list, and be returned every year delinquent for 20 years, and at last be sold by law, when in fact he had no land, and what had been his, had been regularly paid for by the owners. For this and other causes, there was an immense amount of what appeared as land on the tax lists, and which was sold by law without any other mode of designation, and for which deeds were drawn and recorded, that had no existence. The only consolation of the purchaser in such cases, was that he had ventured in a lottery and had drawn a blank—having given perhaps $10, for the chance of finding 1000 acres. But this is a very different situation from the poor duped foreigner who may be the next purchaser, and who relied on the faith of the government for the real existence of, and his indefeasible right to the land.

Within a year or two after the first and great sale of delinquent lands in Virginia, a like sale took place for taxes due to the federal government: and all the real but unproductive lands that had been sold on account of neglect of their owners, by the state, were very sure to be indebted to, and to be again sold under authority of the federal government. In this way, if the purchaser under the first sale bethought himself, after waiting some years, to go to look for his estate, he might find it held by a new owner, who had profited by *his* neglect, as *he* had done by that of the first possessor. Or if years elapse, (as often was the case) after buying an immense number of acres, before travelling to seek them, it might happen, that the original and hereditary possessor, the purchaser under the state law, and the second purchaser under the federal law, might meet, and each one only then discover for the first time that he was not the undisputed owner. But such difficulties have rarely occurred, and perhaps more than from any other reason, because the lands were found to be either in the moon, or on the mountains of Logan, or somewhere else of as little value as if forming a lunar freehold.

But under any circumstances whatever, it is very strange that Englishmen at home can be so gulled—or that any can be persuaded to purchase lands in America at any price, offered to them in London. If a protestant clergyman having a church in the wildest and most lawless part of catholic Ireland, was to offer his claims on his flock for tythes, for sale at auction in the mountains of Virginia, the seller would not give stronger evidence of desiring to sell what was worthless, and the buyer of being a credulous fool, than in the case of land in Virginia being sold in London.

REPLY TO "COMMENTATOR," ON MR. BAUER'S EXPERIMENTS ON DISEASES OF WHEAT.

To the Editor of the Farmers' Register.

Henrico, 9th May, 1835.

In noticing the comments of "Commentator" in the No. of the Register for this month [No. 12 of Vol. II.] on the papers contained in No. 9 of the Farmers' Register, it is not with the view of claiming any merit for the article on the supposed diseases of wheat, &c. over the signature of A. N. contained in that No., but to support the opinion then given of the articles on this important branch of vegetable pathology by Mr. Bauer, contained in the October No. of the Register, copied from the "Penny Magazine." I think it must appear evident to every unprejudiced reader of these articles, that Mr. B. has not only been successful in defining the several diseases therein stated, but in tracing out their true causes; and thereby has been enabled to point out a remedy. If there is nothing wonderful in these interesting experiments, they are at least of sufficient importance to arrest the attention of every farmer. Had Mr. B. merely stated the results of his several experiments, without detailing the way and manner in which they were obtained, there might have been room for continued doubt. But the known celebrity and scientific attainments of Mr. B. coupled with the patient investigation and highly satisfactory results of these complicated experiments, entitle them to very considerable credit. But the true way to test the full value or correctness of these results, and the remedy pointed out, is, for every farmer to try the remedy for himself. Lime water has longbeen used as a preventive from many diseases in wheat, &c.; and many respectable farmers who have used it, have attributed no small degree of benefit to it—but being ignorant of the causes producing these diseases, their remedy—though accidentally the true one, was not used to a sufficient extent to ensure the desired results. But, to use your own words, (in commenting on those experiments,) "these coincidences of accidental practice, with theoretical reasoning, are highly satisfactory; and though in these cases accident had discovered the remedy more early than science had made known the cause, it does not therefore, lessen the value of the latter mode of investigation." There are many farmers who have used supposed remedies for many years, and whom every years' experience must have told was of no use. To such, Mr. B's. experiments must be highly valuable.

I agree with "Commentator" that these and similar dissertations are comparatively useless, unless accompanied by some remedy. I think, however, that the result of Mr. B's. investigations alluded to, clearly points out a remedy, and as such, are of no mean importance. If the pages of every agricultural periodical were filled with dissertations of as important, practical, and decisive a character as are those of Mr. B., I have no doubt that many who are now anti-"book farmers," would be glad to avail themselves of the helps to be derived from such works. I do not think that the reading of quotations such as "Commentator" has favored your readers with, will tend to reduce the "bad odor" of "book farming;" but I do think that the reading to them some such articles as you have happily selected from Mr. B's. productions would; and by inducing them to try the remedy there pointed out, a few converts might be added to this species likewise; and perhaps, a few hundreds of the "thousands" now affected with this unpleasant odor, might be induced to add their names to your list of subscribers, and enable you shortly to carry into operation your proposed improvements on your valuable Register.

A. NICOL.

VITTORIA WHEAT, YIELDING TWO HARVESTS IN THE YEAR.

Loudon's horticultural and agricultural notices, last autumn, gave satisfactory accounts of the experiment tried in Somersetshire, of planting this valuable present made to his country by Sir Robert Kerr Porter, our Consular resident in that part of South America where it is native of the soil. Loudon reports it to have given great promise, both from its spring and summer sowing. In Warwickshire, we ourselves know that it succeeded so well as to produce a fine crop in July last year, though, by an accident, it had been planted a month too late; and it yielded a particularly sweet and well tasted flour, from which excellent bread was made. The proper times for sowing are, February (which gives its harvest in June,) and in June (which yields its harvest in October.)

DESCRIPTION OF A CHEAP WATER-LEVEL, AND THE MANNER OF USING IT.

To the Editor of the Farmers' Register.

In forwarding my annual subscription for your third volume in advance, I embrace the opportunity of tendering my respects to your correspondent M. N., who, in Vol. II. No. 9 of the Register, has added to the stock of information it has already afforded us, on the subject of hill-side ditches, and horizontal ploughing. In place of the rafter level, which is generally used for such purposes, he recommends a plumb level, as described in his communication. I suggest to M. N. as much better adapted to the purpose, a light tin water-level, which can be procured for $1. 25 in Richmond, on the street leading to Mayo's

Bridge, and probably in any other town. It would be found very useful in other operations, such as levelling the foundations for buildings, conducting races for waterworks, or in ditching and draining. It is a tin tube about three and a half feet in length, and three-fourths of an inch in diameter, closed at each end, with a socket affixed at right angles to the centre, for receiving a moveable staff, similar to a surveyor's. At each end of the tube, and communicating internally with it, are two upright tubes or sockets, two and a half inches long, of the same diameter, in each of which is inserted with rosin or some other adhesive substance, a small vial divested of its bottom, and furnished with a cork tied by a string to the neck, to stop it when filled with fluid, thus preventing its spilling when the level is moved. When the operator is to proceed to level a piece of ground, the tube should be filled through one of the vials with some fluid slightly colored; and having fixed his staff, and placed the level on it, he will uncork the vials, when the fluid in them will find a level by having a free communication through the tube, and the two uprights in which the vials are inserted. His assistant will be furnished with a ten-foot rod, graduated with feet and inches, which he will place at the head of a gully or other point where the levelling is to commence, in front of which he will place a piece of paper, which he will move up or down on the rod by direction of the leveller, until the top of the paper ranges with the top of the fluid in the vials, noting the elevation from the earth on the rod. He will then step eight or ten paces, or measure two lengths of the rod on the earth along the course proposed to conduct the levelling, and elevating it to a perpendicular, he will move it up or down hill, until the paper placed at the former elevation ranges with the top of the fluid in the vials. The leveller can, with great ease, move his level to range with the rod, by placing his thumbs on the mouths of the vials, and gently turning the socket on the staff. If it be wished to give a fall or rise of two inches in every twenty feet, it will be readily done by placing the paper two inches higher or lower on the rod, at each removal. In conducting a long level, if it becomes necessary to remove the station of the leveller, the assistant should keep his rod unmoved at his last station, and the leveller should advance beyond him to any suitable position, and sight back to him, continuing the same process as in the commencement. I would make the assistant carry on his arm a basket of small sticks, to mark each station of his rod, instead of employing an additional hand as proposed by M. N. After the line of level is run, the situation of the sticks may be altered at pleasure, so as to produce proper curves, to be followed by the ploughman, who will be accompanied by the leveller, to direct him, and pick up the sticks.

In levelling the foundation of a building, the level is fixed near to it, and the assistant places the end of his rod in a perpendicular position, at any given corner, of the desired height or depth, noting the number of feet and inches where his paper ranges with the fluid in the vials. He then places his staff at another corner, and the range of the top of the water in the vials will immediately inform him whether it be too high or too low, and by how many inches.

In levelling either up or down a stream to ascertain its fall, the assistant places his rod at the water's edge, and the leveller goes forward a convenient distance, sighting back to the rod-man, who notes the height from the water, in a column headed "*back sights.*" The rod-man then goes forward in advance of the leveller, who makes a forward sight, the height of which is also noted under a separate column, headed "*forward sights.*" The leveller then moves his station, sighting back to the rod-man, which is noted as above, who then moves forward in advance of the leveller, and so on alternately, until the levelling is completed, taking care to commence with a back sight, and end with a forward one. The back and forward sights will be equal in number, and after adding up the feet and inches, in each column separately, and deducting the smaller amount from the larger, the difference will be the amount of the fall. If the levelling be up stream, the amount of the back sights will be the larger. The reverse takes place in levelling down stream. The merest tyro in the science of engineering would probably laugh at this communication: but it may, nevertheless, be of service to somebody, in which event my purpose is fulfilled.

SURFACE MANURING.

To the Editor of the Farmers' Register.

The urbanity and scientific research displayed by your correspondent W. B., in his criticisms on my remarks upon J. B's. communications, deserve a very respectful notice. He seems to possess a share of chemical knowledge to which I have no pretensions; and I shall therefore offer little more in reply, than such objections and difficulties as present themselves to my mind, in opposition to his opinions and arguments.

His first observation in regard to the hypothesis which I ventured to suggest, does not appear to me to militate against it. I was well aware of the truth which he states, that "chemical affinity only acts at insensible distances;" and that "the better the mixture of any two things having a chemical affinity, one for the other, the more rapid and perfect their combination." Now it is equally true, according to my hypothesis, that nothing which constitutes the food of plants can combine with the earth, until such substance or substances be dissolved in water. But the water will dissolve them quite as soon while lying *on*, as *under* the surface of the earth, by percolating through the manure; for in both cases this water must at an "insensible distance" from that which it dissolves. The only doubt then seems to be, whether, if the solution takes place below the surface, the food which it contains for plants will not be carried lower into the earth than it ought to be: whereas, when it is absorbed from the surface, it will go no deeper than nature intended it should. As to there being "no gas in the earth," W. B. is right in supposing I did not mean to say so, however my language—never very accurate, might have justified the inference. But my belief is, that the greater portion, if not all of those gases which constitute the food of plants, is imparted to them through their leaves, by the atmosphere, and not the earth, which does nothing more than retain the nutritious water naturally prepared for, and imbibed by the spongioles of the roots of plants. This hypothesis explains satisfactorily, at least to myself, the chief advantage of tillage, which is, that by loosening and pulverizing the earth, the rains and the dews are more intimately mixed with its particles, and therefore longer retained. The other and only advantage is, that none but the plants designed to be cultivated, will receive and share among them, the whole of the food destined for their use.

W. B. has quoted one of Sir Humphrey Davy's opinions, I presume, because he deems it opposed to the hypothesis suggested by myself. If my presumption be right, the quotation furnishes as strong an instance as any I have seen lately, to prove how marvellously men may differ about the meaning of words and sentences; for *I* understand this extract from Sir. H. Davy's Agricultural Chemistry, (so far as it goes,) as sustaining, rather than refuting my own notions. He here asserts the superiority of manure applied in a comparatively *fresh state*, to that which has undergone *much fermentation;* so do I assert it. In what then do I differ from him? Simply in believing that the surface application is better than ploughing it under. But this difference is more apparent than real; for one of his reasons in favor of ploughing under the manure is, that "the fluid matter produced is applied *instantly*, even while it is warm, to the organs of the plant." Now this can apply only to the case of plants growing at the time of the application; but in nearly all the cases which I have supposed, there would be no plants intended for our use growing in the earth, *instantly* to receive this premature supply of food. Again; Sir H. Davy's alleged reason for speedily ploughing manure under, is, that its fermentation above ground would be prevented. So it would be upon *my* supposition, at least all but that fermentation which it undergoes while losing the natural heat acquired in the bodies of the animals that produce it, and this heat it must lose during either process. By being spread on the surface, as in the case of summer cow-pens, or by carting it out as soon as practicable, without heaping, no other fermentation takes place, but that which is unavoidable. But in the other mode, which is to collect and preserve it in heaps, for a considerable time, great additional heat must be generated and continued long enough for the escape of gaseous exhalations to a great and incalculable amount.

The "medical maxim"—"assist nature," which W. B. has suggested, will not, in my humble judgement, assist his argument much: for if the want of skill in applying it be as great among the land-doctors, (and it certainly is so,) as it but too often proves to be in the human-body-doctors, the poor old dame, had she the gift of speech, would not unfrequently have to cry out—"*non tali auxilio—egeo*"—I need no such aid. Fortunately however, in many such cases, if they be not too desperate, her "*vis medicatrix*'," or recuperative power comes in and saves her from destruction. By the way, this business of *assisting nature* is a pretty bold, not to say presumptuous undertaking, let who will attempt it. In the case of an agriculturist, he should be, (if you will pardon a pun,) very sure of his ground, or, he may do much more harm than good: and should he go to acting upon the supposed analogy between his and the medical profession, he may often commit very fatal blunders. For example: "*depletion*" by two or three different modes, is quite a favorite dogma with the faculty, whereas, our mother earth is almost always much more in want of food than physic. Again; medical gentlemen deem themselves bound to invent and apply remedies for all the various diseases and "ills that flesh is heir to;" and as these appear to be innumerable, so, nearly must be the nostrums for their cure. Now the only names of human diseases that can, by any sort of imaginary analogy, be applied to the earth, are, *the gravel* and *the consumption*. The first is nature's own creation, and past all remedy—so far as it impedes vegetation, while the latter is superinduced by the ingratitude of man himself, who, if he had any sense of retributive justice, would most assiduously attempt its cure the moment he discovered any of the premonitory symptoms.

W. B. says, "we might with the same propriety scatter our seeds to the winds, and depend upon the earth, the air, and the rains, to cover, sustain, and mature them," as "to expose manure on the surface:" and *so we might*, if nature's God had not commanded that man should both sow and till the earth, that it may produce the food necessary for his subsistence, which was produced spontaneously before his fall from his primitive state. Let it be borne in mind however, that in all uninhabited countries, as far as we know any thing about them, *every* plant or tree which is propagated by seed of any kind, that grows above ground, deposites them on the surface, where the only covering they get is formed by the falling leaves or rains; but this always proves amply sufficient to continue all their orders, classes, genera, and species, as long as time shall last. I do not mention this as a reason why we should not bury at some depth in the earth, all the seeds we plant, for all men deem this essential: but merely to call W. B's. attention to the fact, that both plants and trees are abundantly perpetuated in every part of the world of which they are natives, without any such inhumation of their seed, as he seems to think indispensable. One obvious reason why we bury them, W. B. appears to have overlooked; it is, that by so doing we can much better bestow on them that cultivation which is designed to prevent any thing else from growing where they do, that they alone, (as I before remarked,) may imbibe the food intended for them.

The inference which he draws from this universal practice of covering seed in the earth being deemed necessary, is, that covering manure is also necessary. But surely this is a *non sequitur*, unless he had proved, that the food of plants contained in manure, could not be imparted to them in any other way. The woody portion of putrescent manures, if left on the surface of the earth, unquestionably requires a longer time to decay than when it is buried below the surface; but in *either situation* it *will* decay. Not until then, can water so act upon it as to dissolve such parts of it as are capable of conversion into the food of plants. The only inquiry, therefore, relevant to the case is, *when* is it best that this solution should take place—some time before the plants to be benefited by it are even so much as planted, (which must be the case with all buried manure, unless it be *that* ploughed under immediately before sowing or planting;) or, that it should take place when, according to Sir H. Davy's dictum, "the fluid matter produced is *instantly* applied, even while it is warm, to the organs of the plant?" Admitting Sir H. D. to be right, I consider the correctness of the latter opinion, to be absolutely demonstrated, so far at least as such assertion can properly be applied to *this*, or any similar subject. To this, however, as to many others, we may truly apply the scholastic adage, "*grammatici certant, et adhuc judice lis est;*" and this being the case, I am determined the present seeming controversy shall, so far as I can help it, "break no squares" between your intelligent correspondent W. B. and your old friend

J. M. G.

THE WHEAT CROP IN FAIRFAX.

To the Editor of the Farmers' Register.

I seeded 290 bushels of wheat after the following manner. Upon the 6th day of October I began to seed upon 87 acres of oat fallow, twice ploughed, which was seeded with 145½ bushels of wheat, consisting of Baltimore bearded, early red, and New York white flint. Two good harrowings put in the seed—all was completed upon the 12th. Fifty acres of this land would have brought good tobacco. The Baltimore bearded is an entire failure, the fly having scarcely left a plant. The early red may make three for one—and the white flint eight for one.

I then seeded a field of 62 acres, dry sandy land, which when enclosed some 20 years past, would produce about 2½ or 3 bushels of corn to the acre. My cattle had been fed upon it for two winters, and it had received much farm-yard litter —and since being enclosed, had received some deep three horse ploughings. Eighty-one bushels of early red was seeded in the field upon two good ploughings, the grain was harrowed in, and all done and finished upon the 20th. This field perhaps is equal to one-half a crop—say 5 or 6 bushels to the acre. The balance of my crop was seeded upon corn land, and completed upon the 6th of November; and may give 5 or 6 for one acre. After this I seeded 40 bushels of rye, which, though young, promises much better than the wheat.

My brother farmers charge the loss of their wheat upon the severity of the winter. This is not my excuse—for the winter passed over us, and left our wheat plants all standing. But nothing in my memory has equalled the destruction of the fly. We have measurably dodged this terrible enemy of late years by seeding after the 8th of October; but they are evidently not to be dodged always—but acting up to the rules of a higher or larger order of devastators, they take all * * I am casting about for a corrective, and think I shall call to my aid 100 acres of rye, which, like the democracy, will overwhelm all enemies, and though the victory will be but rye, it will be exactly that much better than nothing.

X. Y. Z.

Fairfax, May 20th, 1835.

For the Farmers' Register.

ON MAKING RICE ON DRY LAND.

In my paper on the subject of cultivating *corn*, [Far. Reg. p. 634, Vol. II.] I stated the article of *rice*, as entering into the crop. My reason in part, as you will have no doubt discovered, for introducing this article amongst others, was that it is found not to affect in any unfavorable way, the growth of the corn, &c.—and also, that I have satisfied myself, from repeated trials, that this mode of raising it, is calculated to produce that grain in the greatest perfection.

The rice cultivated throughout this state on highland, is in every respect similar to the rice plant of South Carolina. It is found to grow well in every soil we have, from the pipe clay ground of the pine woods, to the black fat limestone land of the great cane brake. In the latter, however, it excels—although from some fair trials I have seen, and indeed assisted in making, I am compelled to believe that pine land, (gray) with a good red clay foundation, moderately prepared by manuring, lime, &c., will equal in production, for quantity or quality, even the fat black land of the great cane brake. It is the most generous grain I know of—will meet successfully a greater variety of seasons and soil than any other. I know of no soil or situation perfectly unfavorable to its production, and it is never made, with our planters, any question in what land they will put it; but what spot is most convenient on the farm of the second year's land. On every species of pine land, with a little cow-penning, cotton seed manure, or any other decomposed animal or vegetable matter, it grows luxuriantly, from four to five and a half feet in height, and produces astonishing crops of grain; say from forty to one hundred bushels of shell rice, that is rice with the husk on, per acre.

The rice produced on our uplands, I am satisfied, is superior in quality to the water raised rice of Carolina—especially that which we raise on the calcareous soils. When boiled in pure water, it exhibits a most decided superiority in the glutinous over the watery principle. I could not possibly admit any comparison in the quality of the two productions. The grain of what we call the "big white," is remarkably large, both in the hull and when cleaned—although the "red bearded" is by some thought superior. Both of those kinds, with the "small white," grow well on dry upland. The operation of hulling or cleaning, is performed with the common pestle and mortar, or in our little tub mills, by partially raising the stones when they become dull and want picking. I have had it cleaned under those circumstances, as handsomely as any table would require.

It may be proper to add, that in boiling the upland rice raised in this section of country, it is found to absorb, or to make a mass at least one-eighth greater than the rice of South Carolina, or any other, where water is employed as an agent in its production.

The straw is found admirable winter forage for horses, mules, oxen, and cows; but especially for young cattle—and a prodigious mass of it is produced from an acre of land. A sheaf of rice passed through the cutting box and given daily, with her other food, to a milch cow, in the winter, is found to produce superior milk and butter. We raise it with so much ease, that we find it economy to give it to our poultry, and pigs, for both of which it is admirable, given in the hull. It is thrashed out with great ease over a bench properly placed, or a barrel.

It is the first article I plant in the spring. If planted alone, and if planted early as possible, it will be off the ground before the arrival of the *rice bird*. Like other grain, I have found it superior, when cut (if for table use,) just *before it is perfectly ripe*. In this case the straw is cured when still *green*, consequently, *highly nutritious*, and when cured still retains its color.

In cultivating this grain, the ground should be turned over in January—harrowed *with* the furrow, and the first favorable state of the *weather* and *soil* in February or March, lay the ground off in drills with a *half shovel*, for the purpose of having the seed deposited as deep as possible, so that, after it is hilled up, the roots may be *deep* in the ground, and which, in case of a *drought* about filling time, will secure it. This last precaution has been the result with me of several experiments. The drills may be as near as eighteen inches apart, if the rice is cultivated alone, and it can be covered with a small board fixed to a scooter plough stalk, or with the hoe or rake. The first is the most expeditious, and requires no other attention than to cover shallow. When six to nine inches in height, plough with a scooter between the rows with a small pony or mule, and finish it off with the hoe, drawing the dirt to it. If the land is light and loose, one ploughing is sufficient—keeping the ground loose and clean is all that is required. It is cut with the sickle, in dry, hot weather, and put up in sheaves the next day, and stacked or housed.

I have had it cut down with the frost twice in the spring, without any bad consequences. I planted once in the *twelve* days, and made a fine crop, remarkable for weight. It was cut down by frost twice; I was making experiments to defeat the *rice bird*, but found that planting in February, or even March, and cutting as before stated, will always find the crop in the barn on his arrival.

I am assured that you will find no difficulty in raising this valuable grain in your vicinity. All difficulty as regards preparing it for table use, is done away, by substituting the wooden block in lieu of the stone—the first being furrowed out in the same manner. Attached to a small horse mill, for my own grinding, I have four pestles, worked in as many mortars, that would clean for a whole neighborhood.

Where I have ground to put in corn of the second year after being cleared, and especially if I can afford a little manure to the land, I would always raise my rice as before stated, with the corn. When the land is not disposed to produce grass, it is made with less labor, for the production, than any crop I know of.

AGRICOLA.

Alabama, March 15, 1835.

SEASON AND STATE OF CROPS DURING MAY—PROSPECTS.

Cold weather has continued to predominate generally through this month, though intermixed in the latter half with some very warm. The corn crops are very backward, and look badly. To cotton, in this region, the cold weather has been still more injurious. But the great loss of Virginia will be in the wheat crop. The Hessian fly has seized on it every where that we have heard from in the state, (probably in consequence of the feeble state of the plants,) and promises to destroy half the remnant that the severity of the winter had spared. The few crops which have come under our personal observation, cannot yield more than half of what might have been expected in a good season—and accounts equally unfavorable—some much more so—have been received in the incidental notices of correspondents from every region of the state where wheat is an important crop. After making due allowance for the fears of writers being heightened beyond the actual and abundant grounds for despondency, it can scarcely be expected that more than half a crop of wheat will be made. A few extracts from private letters will show the kind of information upon which our opinion is founded.

From Goochland, May 19. "Our wheat crops are deplorably bad on James River—the best low grounds even worse than the high lands. I shall now be content with one-third of a crop. The fly has been committing sad ravages for the last ten days; and at the proper time we may anticipate rust. The corn, so far, does not stand very well—and tobacco plants small for the season, and not very abundant; so that really our prospects are gloomy. The oats and clover alone promise well."

A correspondent from the same county, (near Johnson's Springs,) writes (May 18th,) as follows: "The growing crop of wheat is offered by many of my neighbors for the seed sown, and in some cases less. I hope the fatality has not been very extensive, and that other regions may be blest if we are destitute."

Another from King and Queen (May 10th) speaking on another subject, incidentally remarks: "I should like to submit to you and your correspondents, a few inquiries as to the best mode of seeding wheat to prevent its being killed by frost, for my crop, although put in with some care, is an entire failure."

From Fairfax, May 7th. "You may report with safety that not more than a third of a crop of wheat will be made in this county."

From Fauquier an account equally bad was received, but of earlier date. Of the crops of the great wheat growing county, Frederick, something has been stated in the communication (p. 30,) of a "Frederick Farmer"—and a still more desponding view has been given in a private letter from another farmer of that county, dated May 9th.

The bad state of the wheat crop, added to the high price of cotton, (and perhaps also the rising rage for speculation in general,) have combined to give a new impulse to the emigration of the farmers of this state to the South West—and thereby to increase the drain, always flowing from the heart's blood and vital power of Virginia. No country can prosper while continuing to lose annually so much of its accumulated wealth, and so many of its most energetic and useful citizens. It is necessary for those who remain—who will "die in the last ditch" before they will abandon their native land—to use every exertion to aid the general improvement and prosperity of agriculture, as the only means to arrest general ruin—and this end is not more called for by patriotism, than by sound calculations of private and pecuniary interest. *Our* individual share of this general effort recommended, is making through the Farmers' Register—and even that seems likely to be cramped and weakened by the present prospects, and extent of emigration. But this effort will not on our part be relaxed, while its continuance is encouraged by public favor—and if that should cease—this work will at least serve as *our "last ditch,"* in which to die, so far as it relates to service to, or connexion with the public.

From Malte Brun's Geography.

PHENOMENON OF THE BLACK WATERS.

In the upper part of the region of this river (the Oronoke, in South America,) between the third and fourth north parallels (of latitude,) nature has several times displayed the singular phenomenon of what has been named Black Waters. The waters of the Atabaco, Temi, Tuamani, and Guainia, are of a coffee color. Under the shade of the woods of the palm tree their color becomes of a deep black, but in transparent vessels it becomes of a golden yellow color; the images of the southern constellations are reflected in it with singular brilliancy. The absence of crocodiles and of fish, a greater degree of coolness, a smaller number of musquitoes, a healthier air, distinguish the region of the black rivers. They probably derive their color from a solution of carburet of hydrogen, resulting from the decomposition of the multitudes of plants that cover the soil through which they flow.

[The appearance described above is always found in the waters of many sluggish streams, and of mill-ponds or swamps, in lower Virginia. Blackwater Swamp, and its branches, and the lake and canal of the Dismal Swamp, are well known, and remarkable examples. We are not able to appreciate properly the supposition above of the cause of this coloring. But we had before attributed this effect simply to the solution, or suspension in the water, of vegetable extract derived from the vast quantity of fallen leaves and other vegetable substances, over or among which the water flows. The same tinge is often seen in the smallest pools of recent rain water, after standing a short time on poor woodland. So far as our observation has extended, these colored waters are never found, either flowing or standing, over calcareous soil, or where any notable amount of lime in any form is present in the soil; though such soils may be most abundantly supplied with vegetable matters, which yield their extract to every soaking rain. These different circumstances have appeared to us as additional proofs of the chemical power of calcareous earth to combine with and hold this vegetable extract, and to use it for fertilizing the soil—instead of its flowing off, in waste, where enough lime for this purpose is not present. These facts and deductions would have been used as proofs in another place, but for an unwillingness to resort to facts, the extent of which was so imperfectly known. Observing the statement above, has induced us to present the subject here, with the view of its drawing forth further information, or correction from others.]

For the Farmers' Register.

COMMERCIAL REPORT.

The demand for every article of domestic produce continues brisk, and prices generally have advanced. The unfavorable aspect of the wheat crop, gave rise to some speculation in flour, and at one period during this month, the price had risen full one dollar per barrel. Sales were made in a few instances as high as $6.25 per barrel, but some reaction has since taken place, and the price may now be quoted $5.75. It is stated that the wheat crops in the northern and western states are not so much injured as had been apprehended—but there is little doubt that the deficiency in Virginia will be great, and that the market will open at a higher price than for many years.

The price of tobacco has also advanced during the present month. The sales reported at the inspections, embrace all rates from $5.50 to $17 per 100 lbs. Purchases are based, not on the existing prices in foreign markets, but on the expectation of advance; and the spirit of speculation which is unusually active, may not find itself sustained abroad. Such at least has frequently been the result.

Cotton has more than sustained the prices of last month. The current sales in Petersburg of fine quality, have been at 18 cents. Choice has commanded 18½—and the range of quotations is 16½ to 18½. The quantity received in the various ports of the United States to the 1st May, is about 1,130,000 bales, against about 1,000,000 at the same period of 1834. But this success has been in a great measure absorbed by increased consumption.

Stocks of almost every description command high prices. That of the United States' Bank, although its charter is about to expire, has advanced to 113.

The success of the Petersburg Rail Road is pretty well demonstrated by a recent declaration of 4 per cent. dividend for six months, and an advance in the prices of its stock of 15 to 20 per cent. during the current year.

May 27.

TO SUBSCRIBERS AND CORRESPONDENTS.

In consequence of the increased amount of matter recently furnished by our correspondents, most of the pieces have necessarily been kept back longer than has been usual.

To avoid a continuance of such delay, and also for several other considerations of convenience, the 2nd No. will issue on the 15th of June, and the 3rd at our regular time of the 1st of the succeeding month, July—after which the publication will continue, as punctually as before, on the first of each month. With this view, this No., though not issued before June 1st, is dated in May.

GEOLOGICAL SURVEYOR.

Wm. B. Rogers, Professor of Natural Philosophy and Chemistry in the College of William and Mary, has been appointed by the Board of Public Works to make the geological *reconnoissance* of Virginia, as directed by the act of last session of the legislature.

THE FARMERS' REGISTER.

VOL. III. JUNE, 1835. No. 2.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

ON PRICE—THE CAUSES AND EFFECTS OF THE FLUCTUATIONS CONSIDERED, AND THE PRINCIPLES MAINTAINED APPLIED TO THE PRESENT RAGE FOR SPECULATION.

By THOMAS R. DEW, Professor of Political Economy, &c., in the College of William and Mary.

[The following communication was intended by its author to appear anonymously—and it may be observed that its form still accords with that intention—though we have obtained permission to give the author's name. This mark of its origin was desirable, not only for reasons which are sufficiently obvious, but also because the facts treated of are in some degree effects of the causes considered by the same writer in his "Essay on Usury," in Vol. II. of Farmers' Register—and the reasoning of the two communications have a corresponding connexion.

The exhibition of the principles which constitute *price* in general, and the investigation of the causes of unfounded and ruinous fluctuations, may be serviceable to the agricultural community at this time, when there is every indication of the approach of one of those fits of national delusion or madness, such as occured in the time of non-specie paying banks in this country, and such as every commercial country is sometimes liable to suffer from.

In addition to the close connexion of this and many other subjects of political economy with agricultural interests, we find ground for especial approbation of Professor Dew's manner of inculcating his doctrines, by showing their bearing on current events, and offering tests of their truth, in accessible and striking practical proofs. Without resort to some such mode of attracting attention to what is generally (though incorrectly) deemed a dry and repulsive study, the abstract truths of political economy will continue unknown to governments and to nations, long after having been established and undoubted in the opinions of reading men. Thus Adam Smith's exposure of the restrictive (or commercial) system of Europe, had delighted and convinced the learned and literary community, for half a century before it had any effect on the action of the British government—and his admirable work had long been a text book in the colleges in the United States, while our legislators still continued to act, in defiance of its truths, on questions of national policy and in accordance with the notions on trade of the past ages of darkness and ignorance.

Having thus expressed general approbation of the author's views, it is proper to mention an exception—which expression of dissent would otherwise be uncalled for, and unnecessary. It relates to the effects anticipated to Virginia from the present high price of slaves. That such consequences, whether immediate or remote will follow, we have not been convinced by the author's argument.—ED. FARM. REG.]

For the Farmers' Register.

But a little while since, as we all but too well remember, the country was plunged into the utmost distress from want of money, lowness of prices, and failure of credit every where; now we seem to be fast rushing into the opposite extreme—money is becoming very plentiful, prices have almost doubled, and commercial credit seems every where re-established. A speculating mania has been generated in our large commercial cities, and seems rapidly spreading itself through our country. If then this be a season of prosperity, it is one of hazard likewise. Now is the time for the exertion of that prudent foresight and calm deliberation, which alone can carry the man of wealth safely through those great, and sometimes rapid fluctuations of prices, always attendant on the rage for speculation. I propose briefly in this communication to point out the operation of those causes, which are calculated to make money plentiful or scarce, (as it is commonly termed,) and to show their operation on prices at this moment. This investigation cannot, I think, fail to be interesting at this time, and I hope will call forth the speculations of others much more competent to do justice to the subject than myself.

Circulating medium.

The first subject, undoubtedly, to which we must turn our attention in an investigation of this kind, is to the currency. What is the currency? What are the items which compose it? Every thing which passes from hand to hand, and will perform the function of money, must be regarded as currency. First then come the gold and silver coins, and bank paper; these of course form a part of the circulating medium, but not the only, or even the greatest or most important portion. Bonds, promissory notes, scrip notes, bills of exchange, stocks of every description, form likewise a portion of the circulating medium. All of these pass from hand to hand, and represent value, and therefore perform the functions of money. For example, I buy a tract of land, for which I give $10,000, and pay for it by passing to the seller ten bonds of a thousand dollars each. Now this exchange is effected without a single dollar of real money, merely by the agency of credit: in the same way I might have paid for it in stocks, or by giving bills of exchange, &c. But although these are to be looked on as circulating medium, it is evident that equal quantities of them will not perform as many exchanges as money; for the value of money is well ascertained—it bears no interest whilst in our hands, and therefore it circulates rapidly and effects many exchanges: whereas the value of bonds, promissory notes, bills of exchange, stocks, &c., have a value more indefinite; and most of this species of paper too, bears an interest while in our hands. Its circulation is therefore comparatively sluggish, in consequence, first, of the difficulty of fixing its value; and second, because we make a profit on it whilst lying in our hands, and therefore are in no hurry, generally, to get rid of it. But although this portion of the circulating medium be greatly inferior to money in the performance of the functions of circulation, yet it much more than makes up for this deficiency, by the vast amount of it which is in circulation. In England, for example, it has been computed that the bills of exchange alone in circulation are ten times more in amount than the whole money in the country: while the latter is estimated at £40,000,000, the former reaches the enormous aggregate of £400,000,000. In our country, the Bank of the United States alone does a business in exchange, amounting in the year to more than $250,000,000; while its own paper in circulation has never reached one capital, or $35,000,000. Now the bonds, or promissory notes of individuals, may be looked on as rising, in amount, infinitely beyond the aggregate of the bills of exchange and money together. Comparing then all the items of the circulating medium, *exclusive* of money, with the money, we shall be astonished to see how insignificant in quantity the latter is, when compared with the former. The fact is, money performs but few of the exchanges of society, by actual passage from hand to hand. "In England," says Mr. Wade, "by the use of bills of exchange, bills of lading, checks, scrip notes, clearing houses, and a variety of other contrivances, aided by a vast fabric of credit taken and given in open account, money (in its common acceptation,) hardly ever enters into mercantile affairs; it is the substance really meant and shadowed forth; but it rarely, as one may say, bodily passes from hand to hand." In our own country every one too, must have observed how rarely the exchange of large masses of property are effected by the intervention of money. In the great majority of cases, the property is paid for by the passage of bonds, bills of exchange, stocks, &c. and but a small portion by actual money. Hence what are called cash sales, if too frequent all of a sudden, in a particular neighborhood, even in times of great prosperity, will cause the property to be sold at a sacrifice, because of the great difficulty of commanding the actual money to make the purchase.

Effect of rapidity of circulation.

Having thus explained my notion of the components of the circulating medium, and shown that money is vastly inferior in amount to all the other items combined, let us now look a moment to the effect produced on the circulating medium by a rapid or sluggish circulation. And it is very evident, that while the quantity of the currency remains the same, its apparent amount and real efficacy may be either increased, or diminished, merely by an increase or diminution of the rapidity of circulation. For example, $10 passing through ten hands, in the course of the day, will accumulate as much property as $100 passing only once from hand to hand. Now, supposing the whole circulating medium to remain stationary in amount, but that the rapidity of its circulation is suddenly doubled throughout the whole country, then its *apparent* amount, and its *real* efficacy would be doubled likewise. With the help of these incontrovertible principles, let us now proceed to examine into the effect of the late money pressure in the United States. 1st. On the rapidity of the circulation—and 2ndly. On the amount of the circulating medium.

1st. *Effect on circulation.*

I shall not pretend to enter into an investigation of the causes which produced the late pressure in the money market. The nation has already been fully and completely enlightened upon this subject, by men whose minds can compare with any which the world can furnish. Moreover, it would require me to enter more fully into the field of politics, than would be agreeable to myself, or suitable to an agricultural journal. Suffice it to say that the pressure did every where take place; that a general difficulty of procuring money existed throughout the country; that prices, for a season, fell every where; and that confidence and credit for a short time, in the great commercial towns, were almost entirely destroyed. First let us see the effects of all this on the exchanges in society, and then on the rapidity of circulation in the currency.

During a pressure of the kind just spoken of, the loss of confidence and fall of prices, force a great deal of real and other property in the market, to be sold for payment of debts, which ordinarily remains stationary in the hands of its owners. Lands, houses, negroes, stocks of goods, &c., are thus forced to change hands, and of course increase the exchanges. Perhaps the sinking of prices generally may have a tendency to diminish the sales of the annual products of the soil; such as corn, wheat, tobacco, and sugar; but not of cotton, for the foreign market is the regulator of the price of this very important article. Hence it may be said, that a money pressure at first has a tendency, by the great quantity of property forced into the market for sale, rather to increase, than diminish the number of exchanges. Whilst, however, the number of exchanges increase, the circulating medium suddenly becomes much more sluggish, taking the whole aggregate, in performing the functions of circulation. The great capitalists who are in the habit of purchasing produce with a view to sell with a profit, when prices are falling, rather keep aloof from the purchase of raw produce, lest a further fall may injure them—their capital then circulates more slowly, and in consequence of it, the annual productions of the country are not distributed with that regularity, and adaptation to the various wants of the community, as under ordinary circumstances. The body politic in this situation, is like a patient suffering congestion in one part of the system, while there is a depletion almost to the loss of vitality in another.

Again—bonds, bills of exchange, &c., ordinarily performing the larger portion of the circulation of every country, have now a much slower circulation, and consequently less efficacy in effecting the exchanges; because as there is a general loss of confidence and credit, A, who has sold to B, is distrustful of his bonds, his bills, in fine of credit in every shape—he wants money. Money too has generally a sluggish circulation on such occasions, for every one getting possession of it, is disposed to hold it as long as possible—hard money seems to be almost the only true friend which one can get hold of in such times as those, and is consequently held with a miserly grasp. Persons will not venture it out without the best security, and on high rate of interest, obtained either directly or indirectly.*

*An inconvertible bank paper is never hoarded in this manner. It is like fire in each man's hands, he

Thus we find, first, that the number of exchanges has a tendency to increase during the first operation of a money pressure; and second, that the whole circulating medium of the country suddenly, from the very same cause, diminishes in the rapidity of its circulation, and therefore becomes less efficacious, as I have already proved.

2nd. *Effect of money pressure on actual amount of circulating medium.*

Let us now examine into the state of the circulating medium, and see whether during a money pressure, it has any tendency to increase in quantity, so as to counteract the operation of the causes above specified. It is evident, first, that the *money* has no tendency to increase in quantity; because, first, the banks are distrustful of the credit of individuals, and of one another; the curtailment forced on one, communicates to another, and finally all are obliged to curtail their accommodations and issues—hence a decided diminution in bank paper. Secondly, gold and silver in actual circulation diminishes in amount, because of the universal disposition to hoard, in consequence of loss of confidence. Thirdly, bonds and bills of exchange will generally diminish in amount, because these depend on credit altogether, and the first effect of the pressure is the destruction of confidence, and the ruin of the whole fabric of credit. Fourthly, stocks of every description diminish in value, or are entirely destroyed by the disastrous operation of the times. Money, and not stocks, is what the times call for. And thus do we see, that while the exchanges increase, the circulation of the currency grows sluggish, and the quantity in actual circulation rapidly diminishes.

Combined effect of these causes.

What then, let me ask, is the effect of the combined operation of an increase in the number of exchanges, greater sluggishness in the circulation, and diminution of the whole circulating medium? Most undoubtedly, a continued fall in prices, until certain causes are thrown into operation, which will counteract this downward motion. Mr. Hume, in his History of England, says there is a point in the depression of nations, in the scale of circulation, below which they cannot sink. Amelioration will then spring out of the very disorder itself. So I would say, in the disasters of trade and agriculture, there is a certain point of depression below which they cannot go. The self-sustaining energies of commerce are called into play, and apply the healing balm without the interference of government. Thus the causes, whose operation I have just been considering, gave a downward motion to prices in our country, until they reached that point which made this one of the worst markets in the world to sell *in*, and one of the best to sell *from*. The effect of this on foreign exchange will readily be perceived. More commodities were exported than imported. A money balance was created in favor of the nation. Hence a rapid and full current of the metals was soon seen flowing steadily into the country, and supplying the vast deficit in the circulating medium, occasioned by sluggishness of circulation, and diminution of the quantity from general destruction of confidence and credit. We all very well recollect, that a short time since, almost every paper announced the fresh arrivals of cargoes of gold and silver—and we know that at this moment, we have more foreign coins in circulation, than have been seen in the country for years past. The banks too seem generally to have drawn to their vaults large portions of the precious metals.

Effect of importation of precious metals, and of a restoration of confidence.

Now whilst the importation of the metals from abroad is gradually adding to the circulating medium, and therefore partially relieving, by this means, the pecuniary distresses of the country, the number of exchanges in society occasioned by forced sales, will of course have a tendency to diminish, because those sales will become less and less frequent, after the violence of the storm has already prostrated all that could not stand against it. Affairs will soon settle down to this new state of things. Many of the wealthy men of the former epoch, find themselves bankrupts at the commencement of the new—others again who could command a little ready cash during the crisis, find they have suddenly become wealthy. From this point, the operations of commerce once more begin to extend themselves. Confidence is gradually restored, and with it the credit system begins to be built up again, and the large accession of money from abroad, makes the money market much easier than before. The effect of all this is at first to raise prices gradually, and then more rapidly as a spirit of speculation is generated. When prices are sinking, the spirit of speculation sinks likewise, because each individual is fearful of purchasing, lest he be injured by a farther fall in prices. The credit system likewise is greatly contracted, because the rapid fall in prices, and the frequent bankruptcies occurring from day to day, destroy the confidence of man in man.

Now a rise in prices is accompanied with effects the reverse of these. 1st. The credit system becomes instantly enlarged. When prices are rising all are on the alert: the energies of man are drawn forth, his hopes which ever have an undue influence, are thrown into play, and the imagination spreads enchanting schemes and projects before him; he is disposed under those circumstances to rush into business, or to get possession of property, whose enhancement in value from the rising tide of general prosperity, is alone expected to make him wealthy. The borrower now can much more easily get money on loan than before, because general confidence is restored, and the constant rise in prices makes property a good security which before would have been deemed very inadequate. Buying and selling too under these circumstances, will generally be on credit more and more extended in proportion to the restoration of confidence. Now the immediate effect of the extension of credit, and the increased velocity given to the circulating medium, is to produce a superabundance of money. For, recollect I have previously shown that sluggish circulation and the destruction of the

---

wants to get rid of it as speedily as possible, lest it may be caught on him at a still lower point of depreciation. Hence the inconvertible paper of the Bank of England, in 1797, soon relieved the money pressure, but only to bring on evils greater still, as an inconvertible paper always will do.

credit system generated an extraordinary demand for money, which flowed into the country through the medium of importations. The increased velocity of circulation and the re-establishment of the credit system have just the opposite effect, viz: to increase the apparent amount, and the real efficacy of the whole circulating medium. Now when we reflect that the currency has received immense additions during the money pressure from abroad; that the portions hoarded by individuals are thrown into circulation so soon as the panic subsides—that the banks which have rode through the storm are beginning to increase their business and push out their paper, and thus add to the circulating medium; that the United States' Bank has recovered from the shock which it sustained by the removal of the deposites, and is consequently, enabled to do a more liberal and extended business, thereby enabling other banks to enlarge likewise; we are not to wonder under these circumstances, that we have a redundant circulating medium; especially, when we recollect that this increased currency is circulating with greatly increased velocity: and the effect of these combined causes must be a vast enhancement of prices, and a consequent rage for speculation. I will exemplify this by a very simple illustration. Let us suppose a particular neighborhood, whose exchanges in ordinary times, are effected by $1000. Now I have shown if any causes operate to make the circulation only one-half as rapid as the ordinary circulation, then the $1000 will not appear to our little district to be more in amount, or in real efficacy, than $500. In this state of things, throwing out of view all other causes, prices in the neighborhood supposed would fall to half their former amount. Now let us farther suppose that this fall in prices should cause an importation of $500 additional into the neighborhood, and that the rapidity of circulation was again restored. Do we not clearly see that we should have a currency redundant by $500. And this would not only, on the great principle of supply and demand, carry up prices to their former level, but would increase them in the case supposed, fifty per cent. beyond that level. Now what I have been saying here of a neighborhood, may with equal propriety, be said of a whole nation. Let us suppose, for example, the circulating money of this country to be $100,000,000, in ordinary times; that the circulation becomes suddenly only one-half as rapid as before, then the whole $100,000,000, even supposing the quantity kept in circulation undiminished, will perform no more exchanges than $50,000,000 would with the former rate of velocity in the circulation. Prices then would generally sink to half their former amount; money would flow in, let us suppose $25,000,000, and immediately afterwards, the restoration of confidence, and the consequent re-establishment of the credit system would communicate to the circulating medium the same velocity as before, you would then have a redundancy of twenty-five millions of dollars, and a consequent rise of prices at least twenty-five per cent. upon the principle of supply and demand alone. But the probability is, prices would rise greatly beyond this point, in consequence of the effect produced by a speculating mania—for when prices are rising, every one wants to purchase—few are capable of reasoning upon the causes; hence an artificial competition is generated among the buyers and property rises greatly beyond what it should do, upon the principle of actual supply, and efficient demand. The reason of man on these occasions seems to be completely unhinged. He looks forward to the realization of wealth by changes in the price of property which he holds in his hands, and almost every one is disposed to turn speculator. And this speculating mania is generally first felt in regard to stocks, whose value is ever fluctuating, and therefore liable to the most sudden impulses, upwards and downwards. I understand at this moment the stock-jobbing spirit to the north has risen to a most extraordinary height. A gentleman, under date of the 28th ult., writes me from Philadelphia, that rail roads and canals are the order of the day there—that the papers scarcely find room for politics. He says, "two subscriptions have been opened for canals since I came here. The whole stock for the first was taken in thirty minutes. In the second, the whole stock was taken by the commissioners before the doors were opened. A rush and disappointment followed. Millions could have been taken," &c. All this arises from restored credit; from throwing suddenly the hoarded portions of money into circulation—from increased velocity of circulation—from issue of banks, &c., all of which have contributed to make currency redundant, prices exorbitant, and the spirit of speculation wild and reckless. When I saw certain politicians congratulating the nation upon fresh arrivals of gold and silver a short time since, I could not but reflect upon the shallow knowledge of political economy which such congratulations proved. The influx of gold and silver was the clearest proof that could be furnished, of the general distress of the country; of the loss of confidence and credit, and of the stagnation of trade and the circulation. The importation of the precious metals could only be effected by parting with a large portion of our wealth; and as soon as a sound currency and healthy circulation could be restored, this newly acquired portion was to be entirely redundant, and even mischievous in its operation, by raising in the community a speculating mania.

What is to check this rise in prices and spirit of speculation?

I will now examine into the manner in which this rise in prices is ultimately to be checked, and the spirit for speculation to be cured. And here let me observe, that as there is a certain point of depression below which prices will not go, in consequence of the *influx* of precious metals which this lowness of prices will certainly produce; so likewise there is a certain point in the elevation of prices beyond which they cannot well go, because of the *efflux* of the precious metals. It is this efflux which finally checks the speculating mania. I will explain: a rise in prices, when very great, make our country a good market to sell *in*, but a very bad one to sell *from;* hence our imports will greatly overbalance our exports, and a money balance will be created *against* the nation, which must be paid in money. This produces the exportation of money until the redundancy is sent off; then prices fall, and ruin overtakes the most adventurous in the game of speculation—they involve others, and prices once more sink, from loss of confidence and credit, and stagnation in circulation, below their average level, to be brought up again by the operation of causes already pointed out. Whenever the pendulum of price, (if I may use the expression,) has either by the operation of the natural course of events, or by the unwise and unskilful tampering of government, been thrown far into one extreme of the arc, it will, in its effort to regain its natural position, go almost so far into the opposite extreme; and the vibrations will frequently last through a long period of time.

Do these fluctuations depend entirely upon the banks?

Some suppose these fluctuations depend *entirely* upon the operation of the banking system. This however, is not the fact. Banks may do a great deal, but are by no means omnipotent in the regulation of a currency. For example: when loss of confidence, stagnation of circulation, and fall of prices derange the whole credit system, banks are affected like individuals; they are obliged to curtail their operations, and check the farther emission of paper, lest a run upon them may break them. They may not, under these circumstances, have the ability to relieve the distress, however strong the inclination; the relief must come through the wasting process of *buying* metals from abroad. Again: when prices begin to mount upwards, banks by seizing upon the favorable moment, may enlarge their issues, and thus swell still farther the already bloated state of the currency. But they cannot prevent, if they be specie paying banks, the correction of the evil by exportation of the metals; for so soon as these are redundant they will be gathered up for a foreign market; a necessary run will then take place on the banks for the purpose of making the collection, and these banks must either suspend specie payment, curtail their issues, or break. On the first supposition, the evil would have to correct itself by a rise in exchange against us with foreign countries, to the amount of the depreciation caused in the currency by suspension of specie payment. In the second case, prices would be lowered by contraction of the currency from curtailment. In the third, by contraction from the withdrawal of all paper which had emanated from the broken banks and a loss of confidence in the whole banking system, which would, by the runs made upon them, force all to curtail, or break. And thus may we always confidently look forward sooner or later from causes, whose operation I have pointed out, for either a rise in prices when they are very low, or fall when they rise very high. Whenever prices are disturbed, it is a long time before the equilibrium is again restored.

Effect of foreign demand for some of our agricultural products, on present prices.

So far, I have been arguing as if the present state of things were the result solely of that reaction which must sooner or later take place after great depression and stagnation of trade. But the rise in prices may be rapidly accelerated by an extraordinary foreign demand for some of our great staples. Most undoubtedly the rise in the *price of cotton* has at this moment very great agency in the high prices, and rage for speculation manifesting themselves every where. The price of cotton in this country is regulated by the prices abroad, because the foreign market taking up about four-fifths of the whole product of the United States, it is evident that the value of the article must be determined by the foreign, and not by the home demand. What is the cause of the immense rise which has taken place in the price of cotton within a few months I am unable to say. I am not at this moment in a condition to get at the statistical information, required for the investigation of this subject, and my mind not being particularly directed to it, until within a day or two past, I have not noticed from time to time in the papers such articles as might perhaps have given me a clue to the explanation of this interesting phenomenon.—Whatever may be the cause however, whether a general deficit in the cotton crops over the world, or in the United States particularly; or to the rapidly increasing demand for cotton fabrics all over the world; or to a spirit of speculation in England; or to the gradual reduction of the tariff; or to all these causes combined; certain it is, that the price of this most important agricultural staple, is now at a height which well indemnifies the planter for his labor, and will, if it could continue, diffuse wealth and prosperity over the whole of our southern country.

Let us now examine into the influence exerted by this rapid rise in the price of cotton. And in the first place it is manifest, that the rise in the price of cotton must have had a most important influence on the foreign exchanges. This article, alone constituting a very large proportion of the whole of our exports—say two-thirds, a rise in its price has therefore tended to swell the value of our exports, and of course, to make money flow more rapidly into the country—through the agency of a favorable balance of trade. From this cause then, the late money pressure may have lasted a shorter time than it would under other circumstances.

Influence of the price of cotton on the value of slaves.

Again: the rise in the price of cotton has most undoubtedly given an impulse to the price of slaves. Cotton is the great agricultural staple throughout almost the whole of our southern slave-holding states, and consequently, the marketable value of slaves will ever be determined by the value of the principal product of their labor. In Virginia and Maryland the price of slaves will always depend upon the external demand, and not on their intrinsic value in those two states.

If the price depended on the real demand arising among themselves, I doubt whether those states could afford to raise them even: so little would be their marketable value.

But there is another cause which I believe at *this moment* is operating in raising the price of slaves, and will exert a still more powerful influence in future. I mean the late *emancipation of the slaves in the British West Indies.* That act is certainly indefensible upon every ground of expediency, morality, and religion. But its impolicy appears most glaring when considered in a politico-economical light. Now whatever may be said about the relative efficacy and value of free and slave labor, there is no question, but that free labor, produced by sudden emancipation of slaves, is the most worthless and inefficient labor in the world. Let us take upon this subject the testimony of one who has favored emancipation in the West Indies, and who has already reaped some of the fruits of his folly. Lord Brougham in his *Colonial Policy*, says: "the free negroes in the West Indies are (with very few exceptions chiefly in the Spanish and Portuguese settlements) equally averse to all sorts of labor which do not contribute to the supply of their immediate and most urgent wants. Improvident, and careless of the future, they are not actuated by that principle which inclines more civilized men to equalize their exertions at all times, and to work after the necessaries of the day have been procured, in order to make up for the possible deficiencies of the morrow. Nor has their intercourse with the whites taught them to consider any gratification as worth obtaining, which cannot be procured by slight exertion of desultory and capricious industry." The report of the committee of the Privy Council of Great Britain in 1788, of Mr. Braithwaite, the agent for Barbadoes, and of M. Malouet who bore a special commission to examine the habits and character of the Maroons in Dutch Guiana, all agree in asserting that free negroes are idle and worthless, and will never provide for the morrow with the foresight of civilized beings. The latter, M. Malouet says, "Le repos et l'oisiveté sont devenus dans leur etat social leur unique passion." Does not our own experience in this country prove the truth of his assertion? Do we not find the free negro the pest of the society wherever he is seen? He is the same idle worthless creature in the north as in the south and west of our country. Have not the colonies at Sierra Leone and Liberia most conclusively proven the same fact? Does not the example of St. Domingo, which is now but a wreck of its former self, speak volumes on the same subject? Well then, with all these facts and evidences before them, what could British statesmen have foreseen from the emancipation of slaves in the West Indies, but idleness and worthliness of the whole population? and is not this actually the result? Do not all the statements agree in asserting, that the system of apprenticeship has failed to realize the anticipated advantages? and the state of things will be still more deplorable if ever the negro shall obtain his perfect liberty. Now what will be the consequence of all this? Why, that the British West Indies will soon cease to produce sugar for exportation, and will therefore throw the monopoly of its production into the hands of the slave-holding islands, and of Louisiana and the Floridas in our own country; and this will contribute at once to a rapid rise in slave property.

When St. Domingo was first liberated, the imaginations of mere speculative statesmen led them to behold a belt of black republics stretching through the West India Islands, diffusing their moral influence by commerce and social intercourse throughout the habitable globe. Now what was the fact? Why that St. Domingo was soon found to have such an idle, worthless population in her newly emancipated blacks, that her commerce was at once destroyed: she has entirely ceased to export sugar, although formerly the most productive sugar growing island in the world. Under these circumstances, to talk of moral influence, is perfectly absurd. Those black islanders have been by the effects of their own laziness and vices, as effectually cut off from the rest of the world, as if St. Domingo had been enclosed by Bishop Berkeley's forty foot wall of brass. The London Quarterly Review in one of its most powerful articles, asserts, that nothing but the condition of St. Domingo would have enabled the British West Indies to have borne the oppression of the mother country as long as they did; that St. Domingo being thrown out of the competition in the production of sugar, gave a sort of monopoly to the British Islands which enabled them to bear the oppressive regulating legislation of the parliament. Provided we are let alone by the busy meddling philanthropists who can attend to every body's business but their own, every negro that gets his liberty in the West Indies, or in South America, will contribute to a rise, upon precisely the same principles, in slave property in our country. The liberation of the slaves in the British West India Islands, is already producing that effect. If the French, Spaniards, Portuguese, Danes, &c. shall be unwise enough to follow this lead, the southern states of our union will most assuredly reap the benefit; and if Brazil too should follow the example, the effect would be almost complete. It would give us a monopoly in both sugar and cotton. Sugar is not made by free labor any where in the world. Even in China all the sugar and cotton districts are cultivated by slave labor, which, in my opinion, has set to rest forever, in warm countries, the question about the relative advantages of free and slave labor. The cultivation of sugar requires a great deal of hard labor which can be expected of the slave alone. In warm countries the principle of idleness triumphs over that of accumulation, and hence slave labor is universally the most efficient in warm and tropical latitudes. If all the slaves in the West Indies shall ever be liberated, Louisiana will become an *Eldorado*.

Effect of the rise of the price of cotton and slaves, on corn, wheat, tobacco, &c.

The rise in the price of cotton and of slaves is of itself calculated to give an impulse not only to all the agricultural products of the south, but of the north and west likewise, particularly of the west. Corn, which is the great staple of the middle states, is soon raised in value by high prices for cotton; because all the southern country, which is better adapted to the raising of corn than the middle states, raise cotton exclusively, and thus become purchasers of corn. The cultivation of cotton likewise, gradually extends itself even into the middle states, and thus diminishes the quantity of corn raised still farther. In addition to these circumstances, there has been a deficient corn crop for the last two years, in consequence of distressing droughts in the latter part of the season, and too much rain in the commencement. Now we must recollect that in any necessary of life like corn, whose price is dependent on the home demand, if a deficit occur, the price will rise greatly more, than in proportion to the deficit.

The high price of cotton and corn will quickly communicate itself to horses, mules, hogs, cattle, &c., which constitute the great staples of the west: for with corn and cotton high, the middle and southern states will cease, in a measure, to rear those animals, and consequently will become purchasers. Wheat and tobacco depending mostly on the foreign market, will not be so much affected. But as ours is the principal tobacco growing country for all Europe, and as an extension of the cultivation of corn and cotton has a tendency to diminish that of tobacco, it is evident that tobacco would be more influenced than wheat by rise in the price of cotton and corn. Accordingly, we find that tobacco is now selling very high. The high price of cotton is likewise calculated to make the south a better market for all the products of the north, and to give increased activity to the commercial interest, in which the north possesses the deepest stake. Mr. Lee, the author of the celebrated Boston Report on the Tariff, and one of the best statists which this country can boast of, estimated the advantage flowing to the north from the transportation of the cotton of the south, as equal to $5,000,000 on cotton, amounting in value to $25,000,000.

Summary of the causes of the present prices.

Thus have I rapidly sketched out the causes which have been operating in producing the present prices. In the first place, the late removal of the deposites, and the consequent caution and curtailment of business on the part of the Bank of the United States, together with the unfriendly relations existing between that bank and the state banks, which imposed the necessity of a similar curtailment on the latter, gave a shock to public and private credit, which plunged the country into the greatest distress, and rendered the circulating medium scarce every where, by both diminution of quantity, and of the rapidity of circulation. This at once brought down prices to a minimum. The importation of the precious metals from abroad, was the immediate consequence of lowness of prices, and tended to relieve the pressure by increasing the currency. By and by, the banks that rode safely through the storm, began, when things settled down, to enlarge their business, confidence and credit were restored, and a redundant circulating medium is the consequence. This of itself is capable of producing high prices, independent of other causes; but in the present instance, it has been aided by the great foreign demand for cotton, which together with the emancipation of slaves in the British West Indies, has made slaves rise in value throughout our slave-holding country. It has indirectly contributed to the high prices of corn, tobacco, and the staples of the west, and will no doubt, if it continues, diffuse prosperity over all the northern states, in the way I have already explained.

Prospects.

In the mean time let me ask what are our prospects? I answer, that this rise in prices has already excited a rage for speculation which will, in all probability, carry up prices still higher. A fever for speculation, when once excited in the body politic, always produces both economically and morally, the most disastrous consequences. It destroys that regular persevering industry, by which alone a nation can be enriched. It attracts the capital and resources of the country towards chimerical projects, and airy bubbles. During the prevalence of the South Sea scheme in England, hundreds of projects were set on foot—and the sums proposed to be raised by these expedients, amounted to more than $300,000,000, which exceeded the value of all the lands in England. On these occasions, so intoxicated do the people become with a spirit of adventure, that they fall victims to the grossest delusion. Only call it a joint stock company, and thousands of dollars instantly flow into the scheme. All are anxious to enrich themselves by a single stroke of good fortune. The hard-working plodding man is looked upon with contempt. Habits of the most luxurious and vicious character are speedily introduced. There is nothing more true than the old adage, "*easy come—easy go.*" A man who makes a fortune at a stroke, is almost sure to spend it extravagantly. He must live high and give costly entertainments, to purchase the attention and consideration of the new circle into which his wealth has just introduced him. The great merchants, lawyers, physicians, &c., follow the example which is set by the speculators—a reckless profligate gambling spirit is spread through the country—one-half the nation is trying to grow wealthy by the ruin of the other half. Every kind of deception, falsehood, and trickery are resorted to for the purpose of influencing the markets. "During the infatuation produced by this infamous scheme, (South Sea,)" says the historian, "luxury, vice, and profligacy increased to a shocking degree of extravagance. The adventurers, intoxicated by their imaginary wealth, pampered themselves with the rarest dainties, and the most expensive wines that could be imported: they purchased the most sumptuous furniture, equipage and apparel, though without taste or discernment—they indulged their criminal passions to the most scandalous excess—their discourse was the language of pride, insolence and the most ridiculous ostentation—they affected to scoff at religion and morality, and even to set heaven at defiance." A bill was actually brought into the British Parliament for the suppression of blasphemy and profaneness, to so fearful a degree had the spirit of speculation and gambling affected the morals of the people.

The disastrous influence of this rage for speculation in our own country during 1817, 1818 and part of 1819, was almost as great as that produced in England by the celebrated South Sea bubble, or in France by the Mississippi scheme.

With regard to Virginia, I do not think the mania will be so apt to reach her in its most aggravated form. The high price of negroes and cotton, is now producing a fearful emigration to South West, where golden harvests will be realized, if present prices can only be kept up. The spirit for speculation will, in a great measure, direct itself towards south-western lands. Hence although corn, wheat, and tobacco may rise, this exhausting drain of our labor and capital to the south-west, will keep land in this state from rising *pari passu*. Our labor and capital both are swept from our soil as fast as accumulated. At this moment, in Virginia, there is a mighty struggle going on between the elastic principle of the black population on the one hand, and the drain to the south-west on the other. And if the high price of slaves shall be kept up for a few more years, I doubt whether all the procreative energies of the race can compensate for the emigration; and in that event, we shall be obliged to fill up with Irishmen and northern laborers, or leave the soil of the state comparatively stript of labor. In the mean time, however, let us preserve our sobriety, our industry, and our morality; enjoying the present advantages of high prices, without rushing into schemes and adventures of a wild and reckless character, under the vain belief that these times are to last forever. Sooner or later, if prices rise above the natural level, they must come down by a process which I have already pointed out. If cotton shall fall speedily, or if a superabundant corn crop shall be made this year, these extravagant prices would be checked at once. And we must recollect too, that the Bank of the United States is quickly to wind up, and if its curtailment shall be very rapid, it may force the whole banking system of the country to contract its accommodation, and thus perhaps to give a shock once more to public confidence. At all events, let us remember the moral of the famous epitaph—"I was well—I wished to be better—and here I am."

May 21, 1835.

From the Silk Culturist.

LOCUST AND MULBERRY TREES.

The Massachusetts Society for promoting Agriculture, have awarded to Mr. William Clark, Jr. of Northampton, a premium of $20 for a plantation of locust trees. The timber of locust is invaluable on account of its durability. It is sought for by ship builders and the government price for it has been as high as seventy five cents a cubic foot. Locust posts, set in the ground have been known to last upwards of half a century. It is also excellent for fuel. Though the rapid growth of this tree, and its great value renders it a prime object of cultivation, yet the mulberry will be found to be altogether more profitable. Its growth is as rapid—its timber is as valuable, and, in addition to both, its foliage will yield a large annual profit in rearing silk worms. We are credibly informed, that mulberry posts, of the ordinary length and size for fences, have been sold in New Haven for $3 a piece. Every farmer may double the value of his farm in ten years, by cultivating the white mulberry tree, for the sole purpose of timber and fuel.

From the Maine Farmer.

LICE ON CATTLE—NEW WAY TO KILL THEM.

For some wise reason or other, it has pleased providence to create a set of animals in the shape of what are commonly called lice, to live upon other animals. These are often troublesome to farmers. An animal infested with them cannot thrive, keep him ever so well, as another animal kept in the same way that is not infested with them. The natural history, that is, the habits and characteristics of these animals, is not well understood—how long they are in the egg, for they are oviparous—how long it is before they come to maturity and can propagate—how many eggs a female can lay at a time—how long they live if not molested—what they like best and what they hate worst—are questions which every farmer ought to know how to answer, and which we doubt if one in the world can answer. Farmers have different modes of destoying them. *Unguontum*, or *anguintom* as we Yankees too often say, will kill them, and oftentimes the cattle too. It is a preparation of mercury and poison. Bacon fat will kill them. Tobacco juice will kill the old ones and hatch the eggs if put on warm, to our certain knowledge, and oftentimes make the animal tobacco sick—no pleasant feeling. All these preparations are somewhat troublesome to apply, especially the tobacco juice, because the beast must be sopped in the gravy of the Indian weed.

We have been informed that Capt. John Haines of Readfield, has discovered what to us, is a new remedy, and we presume is so to others. It is simply the application of tar in a few spots about the body of the animal troubled with them, and it proves sure destruction to them. If this is a fact, the discovery is a very important one.

ON ORCHARD GRASS.

To the Editor of the Farmers' Register.

Henrico, 9th May, 1835.

If no better reply to the queries of H. P. R. (in the Register for this month) "on Orchard Grass," (Dactylis Glomerata) should offer, perhaps the following observations may be useful to him. Although I have seen this grass extensively and successfully cultivated in this country, yet as my practical experience of it was obtained in Scotland, I shall here give him a statement of the way in which I have there cultivated it, and have seen it done to a considerable extent by others. There we generally sow the seed in the month of March, at the rate of from one and a half to two bushels per acre, with from eight to ten lbs. of red clover seed, (if sown alone, two and a half bushels I believe would not be too much,) having previously steeped the seed in water from six to eight hours. Some prefer moistening the seed by merely sprinkling with water, and keeping it in a damp state for nearly two days. This method, I think, is objectionable; as in that state it is very liable to heat, unless great care be taken of it. After being thus steeped, the seed very easily and speedily takes root. The ground should be well cleaned, and the seed carefully covered in with a light harrow. It has been supposed not to succeed well when sown down with a grain crop; but I have had it sown both with wheat and barley, and always succeeded in having a good crop the succeeding season, which was generally cut for hay. It is a very early grass, and in order to make good hay of it, it should be cut before it gets fully ripe. This must be regulated according to the seasons, and the judgement of the farmer. It will be found generally to succeed well in any soil that will bring a tolerable crop of clover. It is well known as a very valuable pasture grass both for sheep and milch cows; and when early pasturage, or soiling is an object, it will be found to be of great importance. When intended to be cut for hay, it should neither be cut nor pastured the preceding season later than the middle of August—perhaps in this country a month later.

I shall conclude with an extract of a letter from Mr. Falla, Seedsman, Newcastle, England, to Sir John Sinclair as published in the English Farmer's Register. When speaking of the produce of the seed of the orchard grass sown on a square yard as an experiment in a corner of his nursery ground, he says, "in the spring of 1814, it had so abundant and beautiful an appearance, that I was on the 30th of April, (a dry day) induced to cut and weigh its produce, which I found to be 16 lbs., amounting to the astonishing quantity of thirty-four and a half tons per acre; and that at a period when any other green article fit for soiling was not above two or three inches long. I cut it again the 24th of June and obtained eight lbs.; and again on the 10th of September, when I had ten lbs., (both dry days) making a total from three cuttings, of thirty-four lbs., equal to seventy-three tons per acre."

A. NICOL.

From the *Elements of Agriculture*, by David Low, Professor of Agriculture in the University of Edinburgh.

MANURES.

All substances which, when mixed with the matter of the soil tend to fertilize it, are, in common language, termed manures.

Manures may be composed of animal or vegeble substances; or they may consist of mineral matter; or they may be partly derived from mineral and partly from animal and vegetable substances. They may therefore be classed, according to their origin, into—

1. Animal and vegetable manures,
2. Mineral manures,
3. Mixed manures.

In describing this class of substances, it is not my design to treat of their chemical mode of action. This investigation forms one of the most interesting parts of the chemistry of agriculture; but it is not essential to that practical knowledge of the subject which will suffice for the common purposes of the farmer. The remarks to be made therefore, on the mode of action of these bodies, will be of a very general nature.

1st. *Animal and vegetable manures.*—Chemical analysis shows us, that all plants, and all the products of plants are resolvable into a small number of simple bodies, in various states of combination. These bodies are—carbon, hydrogen, oxygen, and in smaller quantity, nitrogen or azote. These form the essential constituents of all vegetable substances. But there are likewise formed in plants, though in comparatively minute quantity, certain other bodies, consisting chiefly of the four earths, silica, alumine, lime, and magnesia, of the oxide of iron, and of the alkalies soda and potassa, but chiefly the alkali potassa.

Now, all these bodies, or the elements of all these bodies, exist in animal and vegetable manures; for these being animal and vegetable substances are resolvable into carbon, hydrogen, oxygen, and nitrogen, with the intermixed earthy and other bodies, existing in the living plants.

In supplying, therefore, animal and vegetable substances to the soil in a decomposing state, we, in truth, supply the same substances which enter into the composition of the living plants. The substances indeed exist in the dead matter of the manures, in states of combination different from those in which they exist in the living vegetable; but still they are present, and must be believed to supply the matter of nutrition which the plants in growing require. Science has made known to us the truth, that the living plants and the dead manures are resolvable into the same elementary substances; but experience has not the less taught the husbandman in every age, that all animal and vegetable substances, mixed with the matter of the soil, tended to fertilize it, by affording nourishment to the plants which it produced.

The simple bodies which form the substance of manures exist in various states of combination, and often in the solid state. Now, there is reason to believe, that, in order that these solid matters may be absorbed by the roots of the growing plants, they must be dissolved in water. The absorbing pores of the roots of plants are so minute, that they are only to be discovered by the microscope. The solid bodies, therefore, which find their way into these pores, may reasonably be supposed to be held in solution by that aqueous matter which enters into the roots of plants, and forms the sap. Water is apparently the medium by which all the matter of nutrition, in whatever form, is conveyed into the roots of plants, and without which, accordingly, vegetation is never known to take place.

Holding this opinion to be just, the substances which form vegetable and animal manures, before they can be rendered available, as nutriment to plants, must be rendered soluble in water.

Of the means which nature employs for this purpose, fermentation appears to be the chief. By this process, the elementary parts of the substance fermented assume new forms of combination, and become fitted to supply the matter of nutrition to plants in that form in which it can be received, by the pores of the roots. The fermentative process is completed after the substance to be used as a manure is mixed with the matter of the soil; but it is common also to cause it to undergo a certain degree of fermentation before it is mixed with the earth. This is the method of preparing this class of manures for use, which is employed in the practice of the farmer.

Animal matters decompose with facility when acted upon by moisture and the air, the greater proportion of their elementary parts making their escape in various forms of gaseous combination, and leaving the earths, alkalies, and carbonaceous matter remaining.

When this decomposition takes place beneath the surface of the ground, these gaseous compounds, as well as the carbon, (which there is reason to believe assumes also the gaseous state by combining with oxygen,) may be supposed to be partially or wholly retained in the earth to afford the matter of nutrition to the plants.

Purely animal substances, therefore, which thus readily decompose, do not absolutely require fermentation before they are mixed with the soil. Yet even in the case of purely animal substances, certain beneficial consequences result from subjecting them to a previous state of fermentation. Thus the urine of animals, when applied in its recent state to the soil, is not found to act so beneficially as a manure, as when a certain degree of previous fermentation has been produced.

And there is another purpose promoted by causing even pure animal matter to undergo fermentation, and this is, that, being mixed with vegetable matter it promotes the more speedy decomposition of vegetable fibre.

Vegetable fibre is, under certain circumstances, a slowly decomposing substance. When vegetables are green and full of juices, they readily ferment; but when the stems are dried, as in the case of straw and other litter, they decompose with slowness, and the mixing them with animal matter hastens the putrefactive fermentation. This mixing of animal with vegetable matter is the process employed for preparing the greater part of the dung of the farm-yard.

The dung of the farm-yard is the produce of the hay, straw, turnips, and other substances used as forage or litter upon the farm. It is collected into one or more yards, and fresh litter and all other refuse being added to the mass, it gradually accumulates, until it is carried out to the fields for use.

The manner of feeding cattle in their houses and yards will be afterwards explained. It is sufficient with relation to the present subject, to observe, that the larger cattle may either be fed in stalls in close houses, or in yards in which they receive their food. When they are fed in close houses, their dung and soiled litter are carried to the heap in the yard, where it gradually accumulates, and when they are fed in the yards, their dung, in like manner, accumulates there, being in the mean time compressed by their treading upon it.

In the practice of the farm, to be afterwards especially described as suited to the circumstances of this country, the larger cattle of different kinds are brought home to their houses and respective yards before winter. Some are kept in their stalls in close houses, and their dung and soiled litter are carried out daily to the yards, whilst others receive their food in the yards themselves, and thus tread upon the heap. In this manner the mass of dung accumulates during the period of feeding, and at the proper period, in the following spring or summer is carried out to the fields and applied to the land.

The dung of the farm-yard is thus sure to be a collection of animal and vegetable substances. It consists of the excrements of the animals kept and fed upon the farm, together with the straw or other materials used as litter, and generally of the refuse and offal produced about the homestead. This mixed mass is collected during the period of feeding, when it undergoes a certain degree of fermentation. When trodden by the feet of the animals kept in the yards, the effect is to exclude the external air, and to prevent the fermentative process from proceeding with that rapidity which would take place were the mass not compressed.

The principal animal substances which are mixed with the ligneous fibres of the litter, and which cause it to undergo decomposition, are the dung and urine of the animals.

The properties of this dung, to a certain extent, depend upon the kind of animals, and the nature of their food. The dung of horses is easily fermented, and is more readily decomposable in proportion to the succulence and nutritive qualities of the food consumed. This also holds with respect to the dung of oxen. When the animals are fed on straw and the dried stems of plants, the dung is less rich and decomposable than when they are fed on turnips, oil cake and other nourishing food; and the same thing holds with respect to the dung of the hog and other animals. The dung of the different feeding animals is mixed in the greater or less proportion with their litter, and the greater the proportion of the animal to the vegetable matter, the more readily will it ferment and decompose.

The urine of the animals, again, is in itself a very rich manure, and contains, in certain states of combinations all the elements which enter into the composition of plants. It is necessarily mixed with, and partly absorbed by, the litter and other substances in the yards, of which it hastens, in a material degree, the fermentation.

The urine however, is apt either to make its escape by flowing out of the yards, or to be imperfectly mingled with the litter. It becomes, therefore, a part of the management of the farm-yard, to provide against either of these contingencies.

The farm-yard should be made level at the bottom and paved if the sub-soil be loose and sandy, and the bottom should be sunk somewhat below the surface of the ground. As a portion of the liquid will flow from the stables and feeding houses, gutters of stone should be made to convey the liquid from these into tanks or other reservoirs adjacent to the yards. The same means are to be taken for conveying away any excess of liquid from the yards themselves. This is not done for the purpose of draining the yards of moisture, which would be an error, but for the purpose of preventing any excess or liquid from being lost. The principal cause which produces a great flow of liquid from the yards is an excess of rain, which, falling upon the heap faster than it can be absorbed, washes away the urine.

Three methods may be adopted for the management of the liquid which is obtained from the feeding houses, or which oozes or is washed off from the mass in the yards.

1. It may be pumped from the tank or reservoir into which it had flowed, conveyed back to the farm-yard, and spread over the surface of the heap. In this manner it will be imbibed by the litter, and tend to hasten the decomposition of the mass.

2. It may be pumped up when convenient, and conveyed in barrels to the field, and spread over the surface, a species of manuring which, under certain circumstances, is exceedingly efficacious.

3. In the bottom of the tank or reservoir to which the liquid is conveyed, may be placed absorbent earths, stems of plants and other matters. These being saturated, will become very rich manure, and may either be carried from the tank to the field, and applied to the ground, or put into heaps or composts, until the period of using them shall arrive.

This method of collecting the excess of the liquid from feeding houses, and yards, is perhaps the best in the common practice of the farms in this country. In Flanders, where extreme care is bestowed in the collection and preparation of liquid manures, there is a smaller proportion of straw and hay produced on farms, than in the mixed system of agriculture of Britain. There is not, therefore, so great a proportion of ligneous fibre to be decomposed. The Flemings, accordingly, pursue the mode of managing their manure, which the circumstances peculiar to their agriculture render expedient. They can always ferment sufficiently the fibrous matter of the heap of their farm-yards, and therefore they have always a spare supply of liquid in a separate state. But in this country, where we aim on producing a large quantity of hay and cereal grasses, we require nearly all the liquid from the feeding animals, to moisten and ferment the general mass of the farm-yard.

When the animals of the farm are fed on tolerably rich and succulent food, and when the proportion of straw is not too large, there is no difficulty in fermenting the mass of the farm-yard to the degree required; but when the quantity of straw is very large in proportion to the more moist and succulent food consumed, as sometime occurs in the case of clay land farms in certain districts, then there may be considerable difficulty in getting the straw sufficiently fermented and decomposed for use. This may arise from want of moisture, as well as from a deficiency of animal matter; and as we may not at the time have the power of supplying the latter, we must endeavor to keep the heap moist by soaking it, in the absence of rain, with water. But the permanent remedy for this evil is to increase the quantity of such nourishing food as the farm will produce—namely, cabbages, tares, clovers, and other succulent and nutritive plants.

Sometimes, even when there is no extraordinary excess of dry litter, the fermentation of the heap in the yard after proceeding to a certain degree, suddenly stops, by which the manure is much injured. This action is termed *fire-fanging*. It arises from the want of moisture, and when it happens it is often very difficult to renew the fermentation. The best remedy is to turn over the heap, soak it with water, and mix it with horse dung, or any animal offal that can be obtained.

With these exceptions, the management of the farm-yard is not attended with any difficulty. We have seen that the mass consists of a collection of the excrements of the animals kept upon the farm, of the straw and other substances employed for litter, and generally of any refuse or offal produced at the homestead; and that this mixed substance is accumulated chiefly during the months of winter, undergoing during this period a certain degree of fermentation and decomposition in the yard where it lies.

The substance thus collected and partially fermented, is to be applied to the grounds during the months of spring, summer, or autumn, immediately following the winter in which it has been prepared. It should be always applied as soon after it is prepared as possible, there being a waste either in retaining it too long, or in causing it to undergo a greater degree of fermentation than is required.

In the process of the putrefactive fermentation, the elements of the body fermented, in assuming their new forms of combination, partly make their escape in the gaseous state. In the fermentation of manures the decomposition may proceed so far that the great mass of the substance shall be exhaled, leaving behind only the earthy and alkaline, and a portion of the carbonaceous matter of which it is composed. In the treatment of this class of substances, therefore, the putrefactive fermentation should neither be continued longer, nor carried to a greater degree than is necessary for the purposes intended.

In practice, our object is to produce certain kinds of crops; and certain kinds of plants, it is found, require a greater action of manures at particular stages of their growth than others. Thus the turnip, the carrot, and the beet, which are sown as will afterwards be seen, in the early part of summer, require that the manure applied shall be in such a state of decomposition as to act upon and nourish them in the first stages of their growth, and if this be not so, the crop may entirely fail. In these and similar cases, accordingly, a complete preparation of the farm-yard dung is an essential point of practice.

Certain plants, again, do not require the same state of decomposition of the dung. Thus the potato requires less in the first stages of its growth, than the turnip, and hence it is not necessary to subject the manure to be applied to the same degree of fermentation.

In some cases, too, as in the process of the summer fallow, to be afterwards described, the manure is mixed with the soil some time before the seeds of the plants to be cultivated are sown. In such case the manure undergoes the necessary fermentation in the soil itself, and does not require that previous preparation which, in the case of the turnip and some plants, is required.

But where no necessity exists for fermenting the matter of the farm-yard beyond the degree requisite for the special purpose intended, it is always a point of good practice to ferment it to that degree. In order to know when dung is sufficiently fermented for the particular use required, a very little practice and observation will suffice. When it is fully fermented, the long stems of straw which formerly matted it together, are in such a state of decomposition, that the parts can be readily separated by a fork. It is not necessary in any case that it be in that extreme state of decay in which we often see it used by gardeners, and when it can be cut with a spade like soft earth. Whenever farm-yard dung has been fermented to this degree, it has been kept beyond the proper time, and the management has been bad.

The mass, we have seen, is collected chiefly during the months of winter, and will always be ready to be applied to the ground in the spring, summer, or autumn immediately ensuing; and there is no case in which it is advisable to keep it beyond the year in which it has been collected.

The common and convenient practice, is to carry it out from the yards where it has been collected, to the field where it is to be used, and there to pile it up in one or more large heaps, so that it may undergo the further decomposition required, before being applied to the land.

When, accordingly, after the dead of winter, as towards the end of December, and during hard frosts and snows, the men and working cattle upon the farm cannot be otherwise employed, we may begin to carry out the dung to the fields where it is to be used. It is carried out in the carriages of the farm, into which it is lifted by large forks to be afterwards described. This partial carrying out of the dung from the yard proceeds when occasion offers, or when the state of the weather prevents the other labors of the farm from being carried on. And when the feeding cattle are finally removed from the houses and yards, and turned out to pasture, which, in the north of England, is generally by the middle of May, the whole remaining dung may either be carried to the fields, or remain in the yards till required for use.

The dung, as it is carried out to the fields, is to be laid in the large heaps, which may be about four, and four and a half feet high, and of such other dimensions as may be convenient. When the dung is placed in these heaps, it is in a state very favorable to further fermentation; for it is to be observed, that in all cases, the turning over of the dung, so as to give access to the air, causes an increase of fermentation, and this is the method adopted by farmers and gardeners, when they want to give a greater degree of fermentation to any heap. Should the dung in these large heaps not ferment to the degree required, they are to be turned over, and formed into new heaps, the upper part being placed below, and what was before below at the top. By this means the fermentative process will be renewed: and should this turning not be found sufficient, the heaps must be again turned over, so that they may be brought to the degree of decomposition requred. The large heaps of this kind should not be placed in a very exposed situation, so as to be too much acted upon by the winds, and it is often a good precaution, and a necessary one in very warm countries, to face up the sides with a little earth or turf and to strew some earth upon the top so as to prevent the escape of decomposing matter. When it is wished to hasten the putrefactive process in these heaps, it is better that they be not compressed by the carriages going upon them to unload; but where there is no peculiar necessity for hastening the putrefactive process, the carriages and beasts of draft can go upon the heap without injury. When peculiar care is required, as when the dung has been injured by fire-fanging, or otherwise imperfectly fermented in the yards, it should be spread over the heap in layers, so that one layer may undergo a slight fermentation before it is compressed by that which is to be placed above it.

Sometimes the mass may be turned over in the yards where it lies, and allowed to ferment before it is carried out to the fields for use. In this case the workmen begin at one side of the heap and with large forks, turn it over, laying that which was before uppermost underneath, so as that the whole may be reversed. If after this process of turning, no treading of cattle is allowed, the fermentation of the mass will proceed with rapidity, and then the whole may be led out at once from the yards to the fields for use.

When the dung produced is very rich and well decomposed, as when cattle have been feeding in stalls on juicy and nutritive food, it may not appear to require this turning over to fit it for use; yet even in such a case it is generally beneficial that it be turned over at least once before being used, the effect being to ferment the mass not only sufficiently, but equally, and to mix its different parts together. It may be observed also, that when the mass of vegetable and animal substances is thrown into a common yard, some care should be bestowed in spreading it equally, so that one part of the yard may not be filled with rich dung, and another with poor. The dung of horses, for example, is more susceptible of quick fermentation than that of oxen. When the stable, therefore, opens upon a common yard, the horse dung should not be suffered to accumulate in a mass about the stable door, but spread abroad upon the heap.

Farm-yard dung is chiefly applied to the soil, by being spread upon the land when in tillage, and covered by the plough. The periods at which this is done, and the manner of doing it, will be afterwards pointed out. By being covered by the earth, the dung soon passes through its course of fermentation, and becomes decomposed and mixed with the matter of the soil.

This valuable substance must be economized in the manner of applying it. The soil must be kept as rich as the means at the farmer's hands will allow; but it is an error in practice to saturate it at one time with manures, and to withhold them at another. They ought rather to be applied in limited quantity, and frequently, so as to maintain a uniform or increasing fertility in the soil.

The produce of the farm-yard will necessarily afford the chief part of the manure consumed upon farms which do not possess extraneous sources of supply. But besides the produce of the farm-yard, there are certain vegetable and animal substances which in their separate states may be applied to the manuring of land. An example of the application of vegetable substances, in this state, is where certain plants are allowed to come in flower, and are then ploughed down in their green state, and mixed with the matter of the soil. This is a practice derived from very ancient times, and is yet followed in Italy, and other parts of Europe.

Vegetable matter when thus covered by the soil in its green and succulent state, readily undergoes decomposition, and forms a very enriching substance. The practice, however, is chiefly suited to the warmer countries where vegetation is very rapid, and even then it argues a somewhat low state of the art, and is not the best way for producing decomposing matter for manures. When we are able to raise green food of any kind, it is better that we apply it in the first place to the feeding of animals, for then it not only yields manure, but performs another and not less important purpose.

When, however, the practice is for any reason adopted, the period at which the plants should be ploughed down is just when they are coming in flower, for then they contain the largest quantity of readily soluble matter, and have the least exhausted the nutritive substance of the soil. The plants employed for the purpose by the ancients were chiefly the leguminous, as the Lupine, which is still used in Italy for the same purpose. Buckwheat is also employed, and appears to be the plant best suited for the practice in northern countries, for it is easily cultivated, and soon arrives at the necessary maturity. For the same reason, spurry has also been cultivated for this purpose: nay, the clovers have been thus employed at the suggestion of speculative writers even in England, and thus the error has been committed of employing a valuable article as a manure, which might have been employed in the first place in supporting live stock of the farm.

The leaves of trees also form a vegetable manure, though not a good one: for although leaves enrich, to a certain degree, the surface upon which they fall and decay, they will rarely pay the expense of collecting them expressly for manuring land.

The roots of plants disengaged from the soil in the process of tilling and cleaning it, are also employed as a vegetable manure. Some of these, however, as the couch grass, being very vivacious, would readily spring again; and therefore it is necessary that their vegetative powers be destroyed, which may be done by mixing them with lime, and forming in this way a compost. Many farmers, however, to save time, or to prevent the risk of the plants springing again, burn them in little heaps upon the ground at the time of their being collected, and spread the ashes upon the surface. This may be sometimes convenient, but the effect is, that the principal nutritive part of the plant is dissipated, and nothing left but the carbonaceous, earthy, and other insoluble matter.

Extracts from the last edition of the "Complete Grazier."

ON THE ECONOMY AND MANAGEMENT OF THE DAIRY.

On the produce of a Dairy.

The produce of a dairy is to be regarded in a two-fold view, as it respects *quantity* and *value*. Both depend in a great degree upon management; for if the cow be injudiciously treated, or the butter and cheese be badly made, both the product and the price will be materially diminished. There is no part of farming more steadily profitable than the dairy; but, at the same time, none demands greater judgement and attention.

Of the three objects of the dairy—selling the milk, or, as it is commonly called, *cow-keeping; making butter and cheese;* and *suckling;*—the first is generally the most profitable, at the usual price obtained for the milk. It can, however, be only carried on in the immediate vicinity of large towns; and even there, the expense of providing fodder, and the fluctuations of its price, while that of milk seldom changes, together with the injury to the health and consequent value of their cows, from the close confinement to which they are usually subjected, and the nature of the food supplied for the purpose of producing an extraordinary flow of milk, often render it a hazardous, and always an unpleasant business.

The making of butter and cheese, which may be distinctively termed *the dairy*, ranks next in the scale of profit; though we cannot but observe that this is contradicted in a late and very minute account of an extensive farm in the Vale of Berkeley, published under the sanction of the Society for the Diffusion of Useful Knowledge.* However this may be, a well fed cow, of a good breed, will produce, on an average, 180 lbs. of butter in the season; and this, where there is an immediate market for it while fresh, together with the value of the skim-milk, either in feeding pigs or making skim-milk cheese, will pay better than cheese alone. The common calculation is, indeed, 150 lbs.;† but this is made upon mixed stock, which afford no certain data. In the Epping district, where no particular attention is paid to the selection of stock, and where there is an indiscriminate mixture of Devon, Suffolk, Leicester, Holderness, and Scotch, the calculation, in a well managed dairy, amounts to 212 lbs.

viz:	
6 lbs. per week, during twenty-six weeks	156
4 lbs. per week, during fourteen weeks	56*

In forty weeks, which is full four weeks sooner than they need be generally allowed to go dry, and there is no doubt that, with proper care in the choice of the cows, and proper pasture to support them, that calculation would be supported in good years; it might not in parching seasons, but then all dairy produce must suffer equally. Mr. Aiton's calculation is, as we have already seen, 250 lbs. per annum; but that is for the best milkers of a very superior stock, and although it may be difficult to reach that quantity in any other than a very select dairy, yet there can be little doubt that, with proper attention to breed and feeding, the Epping average may be maintained.

The same gentleman calculates that 28 gallons of milk produce 24 lbs. of cheese, which presuming, as he does, that each cow gives a thousand gallons in the year, would give 857 lbs. of cheese,‡ and Mr. Ratston, another eminent Scotch dairyman, quoted by Mr. Aiton, says "that he would not keep a cow on his farm that did not yield her own value, or her weight, in sweet-milk cheese every year."

The average product of *full-milk cheese* in the best English dairies, where the whole milk and cream are used, cannot, however, be estimated at more than four cwt. In Leicestershire, indeed, and on other deep grazing soils, that carry heavy stock, a well managed cow is reckoned to make from three to five hundred, long weight of 120 lbs.,§ besides supporting her calf until it can be weaned; but such cows require full three acres of the best meadow, for summer and winter keep, and it is not in the power of every farmer, if he even have the stock, to procure such land to maintain them. In Somersetshire, the average is four cwt. and a half;|| in Essex, not so high;¶ and Mr. Marshall states that of all the midland counties at something more than three cwt.**

---

* See the Report of the Gloucestershire Farms, No IV. in the twenty-first number of the Farmer's Series of the Library of Useful Knowledge.

† In the Sussex Agricultural Survey there is an account of the produce of the Duke of Richmond's dairy; from which it appears that the cows, all Suffolk, produced an average of only 136 lbs. in the season; but it does not mention how they were fed; probably they were pastured in the park.

The same survey mentions a Sussex cow, that for some weeks after calving gave ten pounds of butter, and twelve pounds of cheese per week; and another is mentioned in the Hampshire Report that yielded from fifteen to sixteen pounds of butter, during part of the season: besides many other instances of equally extraordinary produce.

* Essex Agricultural Survey, Vol. II. p. 289.

‡ *Dairy Husbandry, p.* 53. It is much to be regretted that Scotch writers on husbandry do not take the trouble to reduce their provincial weights into the common standard. Three different ones are in use, and unless they are distinctly specified, much confusion is occasioned in calculations: Mr. Aiton's words are "fifty-five pints (*Scotch*) will produce one stone (*county weight*) of full milk cheese." Now the above calculation is grounded on the Scotch pint containing two English quarts, and the Ayrshire stone 16 lbs. of 24 oz. but in some places the pound consists of only twenty-two ounces and a half.

**Rural Economy of the Midland Counties, 2d Edit. Vol. I. p. 326.

Suckling is generally considered the least profitable, as well as the most precarious, both from the accidents to which calves are liable, and the more variable price of veal than of butter and cheese: but it is also the least troublesome; and probably that and the making of butter combined, are the most advantageous; as thus: supposing a steady weekly demand for butter throughout the year, then the most advisable plan might be, to keep such a number of cows as would supply that demand during the winter; and in summer, when butter is cheap and veal in demand, to apply the extra milk, beyond the quantity required for the usual consumption of butter, to suckling calves, either for the market, or for stock, as may best suit the ulterior views of the farmer. This must, however, depend on the situation of the farm; for that may not always afford an opportunity for the acquisition of a succession of calves for suckling, or a market for them when fat; or it may not be adapted for the rearing of stock; and in such cases, the best application of the skim-milk is either to feed pigs, or to make skim-milk cheese. The usual time required for fatting calves for the butcher has been already stated to be ten to twelve weeks;* perhaps less in summer, when the milk is abundant and rich; and more when it decreases in quantity and quality. But as the calf does not require the entire milk of the cow which has calved it, for some weeks after its birth, the cow will, for a short period, support two; and two cows, calving at different periods, may be calculated to fat seven calves between them in the year. Compared with *grazing*, every branch of dairy-husbandry will probably be found the most profitable; but the trouble and difficulty of management so far exceeds the mere feeding of cattle for the shambles, that it can only be carried on, in most instances, to a much more limited extent. It has also the superiority in other points of considerable importance on farms where the mixed system of tillage and grazing is adopted; that it does not require so rich a soil as that for fatting beasts, and that it produces food for pigs, or calves, and thus, by nourishing more animals, creates additional manure and a profitable consumption of the crops on the spot. It has been calculated, that the herbage which will add 112 lbs. to the weight of an ox, will enable a dairy cow to yield 450 gallons of milk; which, upon reference to our previous statements of the average produce of milk in butter, cheese, or veal, and pork, will be found to exceed the return in meat, after making every fair allowance for the additional expense of management. Mr. Aiton estimates it at more than double;† but his statements have been combated, and, to that extent at least, are certainly questionable.

In *feeding pigs*, it has been found that four cows will, in the season, fat a pig of forty pounds weight, to twelve score, which is fifty pounds each cow, besides keeping the calves until weaned: and pigs, it may be remarked, have been fattened to great weights upon milk alone.

Some dairymen allow two hogs to five cows, also rearing the calves; but experience proves, that two cows will support a two year old hog until he is put up to fatten. In the neighborhood of a good market, it will, however, be most profitable to fatten porkers.

Of *skim-milk cheese*, the quantity may be calculated at two cwt. from each cow; but in comparing the two modes of employing the milk, there must be deducted from the product of this application of it the value of the dung that would have been made by the pigs.

Throughout the system of dairy management, the vigilant eye of the principal ought carefully to pervade; as it rarely happens that servants are to be found who will give that minute attention to every particular, which is so indispensably necessary to ensure success. On this account, it is more likely that a dairy-farm of a moderate size—one for instance that will keep ten to twenty cows—will, if well managed, afford a larger proportionate profit than one of a greater extent; because, in the former case, the farmer's wife and daughters can more easily superintend, or perhaps perform a considerable part of the dairy operations themselves; and this always better done by them than it can ever be expected to be by hired servants. No branch of husbandry, in fact, deserves and requires such unremitting attention. "If," Sir John Sinclair very justly remarks, "a few spoonfuls of milk are left in the udder of the cow at milking—if any one of the implements used in the dairy be allowed to be tainted by neglect—or if the dairy-house be kept dirty, or out of order—if the milk is either too hot or too cold at coagulating—if too much or too little rennet is put into the milk—if the whey is not speedily taken off—if too much or too little salt is applied—if the butter is too slowly or too hastily churned—or if other minute attentions are neglected, the milk will be in a great measure lost. If these nice operations occurred only once a month, or once a week, they might be easily guarded against; but, as they require to be observed through every stage of the process, and almost every hour of the day, the *most vigilant attention* must be kept up throughout the whole season. This is not to be expected from hired servants. The wives and daughters of farmers, therefore, having a greater interest in the concern, are more likely to bestow that constant, anxious, and unremitting attention to the dairy, without which it cannot be rendered productive."*

From St. John's Egypt.

VISIT TO THE EGG-HATCHING OVENS OF CAIRO.

The hatching oven consists of a suite of small square chambers, or cells, arranged on either side of a small passage, in which they open; the doorway, when there are eggs within, being closed with mats. In some of the chambers the eggs had been newly put in, and were perfectly white; in others, having already undergone many changes, they exhibited a dirty yellow color; while in several cells, the embryo having been warmed into life, had shattered its prison, and was emerging through the broken shell. Nothing is more common than the process of incubation, which, in fact, falls under the eye of every man; and the principle of the Egyptian hatching ovens, in which a heated atmosphere performs the office of the hen, is also generally understood; yet I could not behold without admiration a thick stratum of eggs, acted upon by an invisible fluid, bursting into spontaneous motion, rolling against each other, cracking, opening, and disclosing each an organized and animated being. As soon as the chickens are out of the shell, they are carefully removed into the passage, which is divided into numerous compartments by small ridges of clay; from whence, when a few days old, they are drafted off into cooler quarters. The passage, at the time of our visit, was filled with chickens; of which there must have been many thousands, not more than one day old, chirping, moving about, and nestling against each other. Stones placed at intervals, like stepping stones in a brook, enabled us to traverse the several compartments. A number of low subterranean cells, in which an equal temperature is maintained by fires of dung, communicate a sufficient heat to the hatching rooms by apertures in the floor. Few persons can endure, for any length of time, the intense heat of these ovens. We were glad to make our escape; and, on issuing forth into the streets, after making our saucy Arab a handsome present, we found the atmosphere of Cairo, at noon, cool and refreshing. Respecting this process, many erroneous ideas are prevalent in Europe. It has been supposed that the secret, as it is termed, is known only to the inhabitants of a few villages in the Delta, who, dispersing themselves over the country in autumn, undertake the management of such eggs as are entrusted to their care; but there is no secret in the matter, and the eggs are thus hatched by the inhabitants in all parts of Egypt. In the oven we examined there were at least twenty cells, each, perhaps, containing five thousand eggs; so that, should they all take, one hundred thousand chickens would be produced in twenty-one days; or one million seven hundred thousand per annum, supposing the process to go on without intermission. Two hundred similar ovens, kept in constant operation, would therefore hatch, in the year, three hundred and forty millions of chickens!! so that were this practice introduced into England, it would very speedily reduce the price of poultry.

From the Vergennes Gazette.

MANAGEMENT OF (IRISH) POTATOES, TO PRODUCE CROPS UNUSUALLY LARGE.

Mr. Blaisdell—In your paper of the 21st December last, I published the result of some experiments made during the season, in growing potatoes. The quantity produced was such as to cause considerable excitement with agriculturists, and I have been called on by public journals and private letters from Maine to Georgia and from Quebec to Malden, for information respecting my manner of cultivating them. The respectability of the sources from which these inquiries emanate, and the very polite and flattering terms in which they are expressed, forbid the idea of refusal. I therefore embrace the first opportunity my health admits of attempting to gratify their wishes, to the extent of my limited powers.

From the remarks of some of my correspondents I am inclined to believe they misconstrued the statement made in the publication above alluded to. By reference to the statement it will be found that I did not say, or expect to be understood by field culture, that 1,800 bushels of potatoes would be raised upon an acre. I then said as I now say and believe, that 1000 bushels can be grown upon a single acre at less than half the expense and labor they are produced from four in the common manner of culture.

Preparation for planting.

Whatever soil may be selected for this purpose to insure a large crop, it should be highly manured with compost, decomposed vegetables or barn-yard manure, the latter I consider preferable when it can be obtained with convenience; if raw or coarse be made use of, it should be spread immediately before the first ploughing, on the same day, to prevent the evaporation of its best qualities, which will rapidly depart if left exposed to the sun and atmosphere.

The first should be deep ploughing, and may be done as early as suits the convenience of the cultivator. If a stiff marl or clay soil, it would be well to have it ploughed late in the fall previous to planting. Where compost or other substances not liable to fermentation are intended as a manure, it is better the spreading should be omitted until just before the last ploughing, after which it should be thoroughly harrowed fine and smooth as possible, then take a narrow light cultivator, or small plough, calculated for turning a deep narrow furrow, with this instrument lay your land in drills, twenty inches asunder and four inches in depth, running north and south if practicable, to admit the rays of the sun to strike the plant equally on both sides; put into the bottom of the furrows or drills about two inches of well rotted barn-yard manure or its equivalent, then drop your potatoes, if of the common size, or what is more important, that they contain about the usual quantity of eyes; if more, they should be cut to prevent too many stalks shooting up together. Put a single potato in the drills or trenches 10 inches apart; the first should remain uncovered until the second one is deposited. Place them diagonally in the drills, which will afford more space between the potatoes one way, than if laid at right angles, in the rows. The covering may be performed with a hoe, first hauling in the furrow raised on each side the drill, then carefully take from the centre of the space the soil to finish the covering to the depth of 3½ or 4 inches. By taking the earth from the centre of the space on either side, to the width of three inches, it will leave a drain of six inches in the centre of the space, and a hill of 14 inches in width, gently descending from the drill to the drain; the width and depth of the drill will be sufficient to protect the plant against any injurious effects of a scorching sun or drenching rain. The drains in the centre will at all times be found sufficient to admit the surplus water to pass off. I am not at all tenacious about the instrument to be made use of for opening the trenches to receive the manure and potatoes; this work should be well done, and may be performed with a common hoe, with much uniformity and accuracy, by stretching a line to direct the operation: it is true that the labor cannot be performed with the same facility as with a horse, but it can be better done, and I think at less expense, taking into consideration the labor of the man to hold, the boy to ride, and the horse to draw the machine.

Dressing, hoeing etc.

When the plant makes its appearance above the surface, the following mixture may be used: For each acre, take one bushel of *plaster* and two bushels good ashes and sow it broad cast as even as possible. A moist day is preferable for this operation—for want of it a still evening will do.

I consider this mixture decidedly more beneficial and much safer than plaster or ashes alone. The alkali and nitre contained in the ashes lose none of their fertilizing qualities in a moist season, and the invaluable properties of the *plaster* are fully developed in a dry one, by decomposing the atmosphere and retaining to a much later period in the morning the moisture of the evening dews. There are but few plants in our country that receive so great a share of their nourishment from the atmosphere as the potato. The time for dressing or hoeing will be found difficult to describe and must be left to the judgement of the cultivator; it should however, in all climates be done as early as the first buds for blossoms make their appearance.

The operation of hilling should be performed once and *once only* during the season, if repeated after the potato is formed it will cause young shoots to spring up, which retards the growth of the potato and diminishes its size. If weeds spring up at any time, they should be kept down by the hand or hoe, which can be done without disturbing the growing stalk.

My manner of *hoeing* or *hilling* is not to haul in the earth from the spaces between the hills or rows, but to bring on fresh earth sufficient to raise the hill around the plant $1\frac{1}{2}$ or 2 inches. In a wet season, the lesser quantity will be sufficient; in a dry one the larger will not be found too much. The substance for this purpose may consist of the scrapings of ditches or filthy streets, the earth from a barn-yard that requires levelling, where convenient it may be taken from swamps, marshes, the beds and banks of rivers or small sluggish streams at low water. If planted on a clay soil, fresh loam taken at any depth from the surface, even if it partakes largely of fine sand, will be found an excellent top dressing. If planted on a loamy soil, the earth taken from clay-pits, clay or slaty soil will answer a valuable purpose; in fact, there are but few farms in the country but what may be furnished with some suitable substance for top dressing if sought for. The hoeing and hilling may be performed with facility by the aid of a horse and cart, the horse travelling in the centre of the space between the drills, the cart wheels occupying the two adjoining ones, thereby avoiding any disturbance or injury to the growing plants. The time for collecting the top dressing may be regulated by the farmer's own convenience; the earlier the better. Deposited in large piles in or near the potato field, is the most suitable place for distribution.

I have frequently tried bed-planting, (or planting in beds) with uniform success. On moist lands in a stiff or heavy soil, I consider it preferable to any other mode; to do it properly lay your land in beds of from 10 to 20 feet in width, raised in the centre with a plough by back furrowing, after the last harrowing which should be thoroughly done is performed and left crowning with a gradual descent from the centre to the alleys; the proper width and heigth of the beds must depend on the situation of the land and may be regulated by the judgement of the cultivator. In clearing the alleys, which need not exceed 16 or 18 inches in width, the laborer should stretch two lines the proper distance on each side the alley and throw upon the beds with a shovel the earth necessary to be removed.

The use of lines may be by some considered a useless expenditure of labor—not so—the regularity and neatness of appearance will be an abundant remuneration for the trifling time occupied in stretching the lines.

After the land is prepared for planting, strike it out in drills or trenches as before directed; 12 inches asunder, in these drills, drop the potatoes 12 inches a part (diagonally,) to be covered, hoed, dressed and managed in the same manner as in field culture, with the exception of making an undrain in the spaces between the drills, which is unnecessary and should be avoided. In filling the trenches, dressing, &c. the horse-cart must be dispensed with and a hand-cart or wheelbarrow substituted.

In recommending the drills north and south in field planting, I did not wish to be understood that other more valuable considerations should be abandoned for this practice: it is desirable it should be so where the level or moderate descent of the land will admit of it, but if too steep and liable to wash, care should be taken to avoid this evil by running the drills in such direction as may be required to maintain a proper descent, even if it should be necessary to run them in curved lines, or wind around a steep hill to preserve the required descent to admit the surplus water to pass off.

In communicating my experiments to some of my neighboring farmers who are always in a hurry and run over with the plough two acres of land in half the time required to do justice to one; their reply generally is, that my tedious mode of cultivation has too much *piddling* and small labor for patience, and persist in their accustomed manner of half ploughing, half planting and half hoeing five acres of good land and not obtain more potatoes than one, properly cultivated, would produce, thereby losing half their labor and seed, besides the use of four acres of their best land, which might be converted to other valuable purposes.

I should think that intelligent farmers by a little reflection would perceive the folly of pursuing the usual wasteful practice of planting potatoes in rows and hills four feet asunder, having four-fifths of their land unimproved and subject to a rapid waste of its most fertilizing qualities by being nakedly exposed to the washing of drenching rains and the evaporation of the atmosphere; and after all their labor, may consider themselves fortunate if they obtain 200 bushels to the acre, which exceeds the average yield in this section of country. By pursuing the course I have recommended, in ordinary seasons on a good soil you may rationally calculate on a crop of from 800 to 1200 bushels to the acre.

To such farmers as complain of my tedious and piddling mode of culture I have only to remark, if they will *piddle* their land in the same manner, even if they waste half their crop, they will find themselves richly rewarded for their whole labor, in the benefits they derive by this preparation in succeeding crops. I would also add that I believe it generally acknowledged, that rotation in most kinds of crops is desirable, but none more necessary than potatoes, even a second crop on the same ground well prepared will be found to degenerate in quality and quantity.

Location.

The district of country in North America best adapted for their growth, taking into consideration quantity and quality, is situated between the 2d and 10th degrees of east longitude (from Washington) and between the 42d and 50th degrees of north latitude; they are grown to a very considerable extent much farther north, south, and west, but in diminished quantities and inferior qualities.

Soil.

A rich marl or clay is perhaps the most productive; a strong moist loamy soil, (the newer or less it has been cultivated the better) is the most convenient and least expensive soil to grow them on. Most soils common to our country will produce them in great abundance and perfection, the more rapid the growth, the better the quality.

Season for planting.

In this respect they are a most accommodating crop, allowing the farmer in the southern and central part of the designated district, 20 or 30 days to perform the operation: the particular part depends in a very considerable degree upon the climate. In the region of my residence, the 44th degree of north latitude, they may be planted from the 10th of May to the 15th of June. At the extreme north of the described limits less latitude is afforded for seed time and harvest. The good husbandman in that climate should make all practicable preparation for his crop in the fall, and plant as early in the spring as the ground is sufficiently dry and warm; here the growth is extremely rapid, not requiring more than from 90 to 110 days to perfect it; the quantity will not be quite so great as with us, but superior in quality.

Kind of seed to be planted.

This is a question of too much difficulty for me to answer satisfactorily to myself, or instructive to the numerous inquiries of my correspondents; the kinds and qualities in a single neighborhood are too numerous and their names too local and variable to admit of an intelligent reply.

The female of this plant, like most of her sex, is so jealous of her rights and privileges and so tenacious of cultivating a friendly intercourse and connexion with the neighbors, that the blossoms in fields at 200 yards distance, planted of different kinds of seed, are frequently found contributing liberally with each other, by the aid of a gentle breeze, a portion of their generating *Farina*, which is generously received and kindly nourished; the product of this connexion strongly partaking of the properties and appearance of both, many of them in apparent equal parts. Plant this mixture a few years in a place of safety and it will be found that the weaker plant will gradually yield to the stronger, until the one most productive and best suited to the climate will be produced in its original and unadulterated purity. The fact goes far in satisfying me of the cause of our frequent disappointments in not finding seed at all times producing its kind. We have abundant means with a little care and patience of supplying ourselves with every variety of potatoes, the growth of which is adapted to our climate.

The wise provider of all good things has kindly furnished us with the means of providing ourselves with innumerable kinds and qualities of this vegetable. The ripe balls or seeds from a single stalk, will produce by three seasons' planting, almost countless varieties of every color, shape, size and quality, which the country has heretofore produced, and something new, in addition.

The first season's planting they will be small and tender, the second larger, and the third of suitable size for field planting.

The only answer I can give to the inquiry for the right kind of seed, is to recommend to the farmer that kind to be procured in the vicinity, most productive, except a small quantity if he possesses them, of a superior quality, for table use. In changing seed, which will occasionally be found beneficial, if removed from any considerable distance, should be taken from the north: the growth will be more rapid, consequently, the quality better, and in southern climates the quantity greater for the first season, at least.

Time for gathering

This ought to be done when the potato is ripe and not before. The idea so generally entertained that an early frost which nips the top and destroys the vine, prevents the further growth of the potato is a mistaken one, and ought to be exploded; on the contrary, if it has not at this time attained its full size and weight, it grows more rapidly; the nourishment required for sustaining the top is transferred to the root. From a knowledge of this fact, satisfactorily tested, I am inclined to believe that by clipping the bushy part of the top with a scythe or other instrument, after the ball has attained its full size, the crop would be greatly benefited by the operation. I have made a few experiments of the kind, all tending to confirm my belief, but not sufficient to warrant me in making the broad unqualified assertion of the positive correctness of my opinion. I hope agriculturists in different sections of the country will lend a helping hand to aid in testing the correctness or incorrectness of my doctrine in this particular. The green tops are excellent food for cattle or swine; if left on the field will produce no injury, but serve to enrich the soil.

Housing and wintering.

The erroneous practice pursued by our best farmers generally, induces me to state the manner I have pursued for years with unvaried success. To preserve 5 or 600 bushels, I make a box or bin four feet wide, three feet high, and sufficient length to contain the required quantity—have the joints well fastened and made as tight as possible, put into the cellar on skids, raising it three or four inches from the cellar bottom; if the potatoes are intended to be taken out at different times, two or three partitions should be put in cross wise of the bin, to prevent such as are not required for immediate use from exposure to the atmosphere. After this preparation is completed, the next operation is gathering and housing them. Here I must again dissent from the usual practice of farmers generally; instead of leaving them in the sun and wind to dry, after digging, in small parcels, in carts or heaps, they should be immediately covered with the tops or something else, even if they remain in the field but a few hours. This destructive practice, I think must be entirely attributable to want of reflection. It is the sole cause which produces the evil so much complained of, by us called, the watery potato; by the Irish, the winded potato: destroying not only the flavor, but a great portion of its nutriment. In fact, sun, wind and rain, are as destructive to a fresh dug potato, as moonlight is to a fresh caught fish. When our potatoes are removed to the cellar, put into the bottom of the bin two inches of fresh earth, then fill your apartment with potatoes, within three or four inches of the top, immediately cover it with tough grass turf, cut up with a spade a little dove tailing, to the thickness of three or four inches: cover them with the turf, grass side up, packed close and pounded down with a wooden mall, to exclude as much air as possible. In this manner in a cellar of suitable temperature, they may be kept fresh and good for a year, without germinating. No danger is to be apprehended of having too much dirt sticking to the potatoes, it assists in preserving them; an occasional sprinkling of fresh earth amongst them will be found serviceable.

* * * * *

A. W. BARNUM.

Vergennes, March 13, 1835.

Extracts from an Essay by M. Arago in Jameson's Philosophical Magazine.

ON ARTESIAN WELLS.

Depths of the most remarkable Fountains which have been opened by the hand of man.

We have already alluded to pits sunk by the Chinese to the depth of 1800 feet, in the province of Kia-ting-fou, by which they hoped to procure a supply of salt water; but as no water ascended the pits, we cannot rank them in the list of wells properly so called.

The seventh sheet of water, found near Saint Nicolas l'Aliermont, was at the depth of 1030 feet. The water from it rose to the surface. As it was not water, but coal, that was sought for, the works were abandoned; and the only result that remained, was the formation, without intending it, of a copious fountain, whose waters issued from a source more than 1000 feet deep.

The pit recently sunk at Geneva to the depth of 682 feet, has not reached any body of water which has a tendency to rise.

At Suresne, near Paris, the residence of M. Rochschild, the Messrs. Flachat have worked a pit, previously begun by M. Mulot, to the depth of 663 feet. This pit has now penetrated the chalk to the extent of 537 feet. The work has been suspended, when there is only 60 feet more of the chalk formation remaining, upon penetrating which, there would be every prospect of finding water. The desirableness of prosecuting the research is most apparent.

The fountain of Cheswick, in the Duke of Northumberland's park, projects its water about a yard above the surface of the soil, and comes from the depth of 582 feet.

The deepest fountain in the department of Pas de-Calais is situated between Béthune and Aire. Its waters project seven feet above the ground, and come from a depth of 461 feet.

The artesian well which affords such an abundant supply in the cavalry barracks of Tours, is fed by a body of water which M. Degousée found at the depth of 259 feet. The water of another well, which was finished in 1834, in the silk manufactory of M. Champoiseau, springs from a depth of 273 feet.

Concerning the daily issues from some of the principal Fountains.

Belidor has already mentioned, in his Science de l'Ingénieur, a fountain which is situated in the monastery of Saint André, a couple of miles from Aire in Artois, the waters of which rise to the height of eleven feet above the ground-floors, and which furnishes nearly two tons of water per minute.

The well which Messrs. Fabre and Espériquette have sunk, at Bages, near to Perpignan, in the property of M. Duvand, supplies 333 gallons per minute.

The well which M. Degousée had sunk in the cavalry barracks at Tours, measured at six feet above the ground, furnishes 235 gallons per minute.

Of the many wells which exist in England, the one whence, according to my knowledge, there is the most abundant supply of water, is that in the copper manufactory of Merton, in Surrey; its issue amounts to 200 gallons a minute.

The artesian well of Rivesaltes, for which the inhabitants are so much indebted to Messrs. Fabre and Espériquette, engineers, furnishes 176 gallons in the same time.

The well lately sunk near to Lillers, in the department of the Pas de-Calais, with a depth of 140 feet, affords a supply of 155 gallons per minute.

Of Artesian Wells whose waters have been employed as moving powers.

At the village of Gouéhem, near Béthune, four wells have been sunk in a meadow to the depth of 120 feet. The waters which issue from them are converted into the water-course of a flour-mill, and subserve other agricultural processes.

At Saint Pol, there is another mill, the only moving power of which is the water from five projecting fountains.

At Fontès, near Aire, the waters of ten such wells are made to turn the mill-stones of a large mill, as also to blow the bellows and beat the hammers of a nail manufactory.

At Tours, M. Degousée has excavated a well, in the silk manufactory of M. Champoiseau, to the depth of 430 feet, which pours 287 gallons of water per minute into the troughs of a wheel of twenty-one feet diameter. This wheel works the looms of his manufactory.

At Tooting, near London, the fountain of an apothecary puts a wheel of four feet diameter in motion, and this sets a pump to work, which raises water to the top of a house three stories high.

Of the advantage to which industry, in various circumstances, has turned the waters of fountains.

On the present occcasion we need not dilate on the benefits these waters confer on public health, nor on their use in irrigation, &c. &c. We shall only point out their application to a few purposes which are less generally known.

These springs have been put in requisition even in countries where more commcn water-courses are not unfrequent. Their constant and high temperature permits them to be applied to the movement of machinery during the most severe winters, whether it be directly, when they are abundant, or in other cases, only as a means of washing away the ice, which is apt to stop the movement of the water-wheels.

In Wurtemburg, M. Bruckman, by transmitting through metallic pipes, conveniently placed, a current of water, at the temperature of 54° Fahr., which is derived from several natural springs, keeps up a temperature at 47°, in various manufactories where the external cold lowers the thermometer to zero. This is a simple imitation of a plan which has been long practised in the village of *Chaudes-Aigues;* the results, however, are worthy of consideration.

Greenhouses also are in existence, in which the temperature is maintained very equally, by the effects of the constant circulation of a large quantity of water, derived from these sources.

During heavy rains, the work of paper-mills is often interrupted, on account of the impurity of the water. These forced stoppages come to an end, when the constant limpid supply of a projecting fountain can be employed.

In some localities the invariably pure waters of a steady temperature, proceeding from these springs, have been the means of establishing very lucrative artificial cress-plots. The beautiful growth of cresses in those parts of the beds of rivulets where these natural springs existed, has suggested this application. It is positively stated that the artificial cress-plots of Erfurt yield not less than £12,000 per annum.

The very fine lint which is intended for the manufacture of cambric, lawn lace, &c. is steeped in the department *du Nord,* with very particular care. In a single *commune,* between Douai and Valenciennes there are ten or a dozen retting-pools, which are fed entirely by water from the projecting fountain. It has been thought that the purity of these waters, and the invariability of their temperature, by accelerating the solution of the gum-resins, preserve the valuable qualities of the filaments of the lint in the highest degree of perfection.

In fish ponds, the fish are apt to die during the winter, from the severity of the cold, and in summer from the heat. By turning the invariably temperate waters of an abundant artesian well into them, the extreme variations which the seasons induce are prevented. This experiment, it is said, has entirely succeeded in the ponds of St. Gratian, near to Montmorenci.

Caverns into which whole rivers are engulfed.

This phenomenon in a high degree excited the attention of the ancients. Thus even Pliny mentioned as among the rivers which disappeared under the surface of the earth, the *Alpheus* in the Peloponnesus, the *Tigris* in Mesopotamia, the *Timavus* in the teritory of Aquillia, &c. He also ranks the Nile in the same class, for, according to him, it disappears for the space of three day's journey before its entrance into the Cesarian Mauritania, and also to the extent of twenty days' journey upon the frontiers of Ethiopia. Come we now, however, to examples that are nearer to ourselves, better determined, and more known.

The Guadiana loses itself in a flat country in the midst of an immense meadow. Here we have the explanation of the fact, that, when we are speaking with admiration of some superb bridge in France or England, the Spaniards remark that they have one in Estremadura upon which a hundred thousand head of cattle can feed at the same moment.

The *Meuse* disappears at *Bazoilles.* It would appear that it is only in later times that this has been the case, for, according to M. Hericart de Thury, although the original bed is now cultivated, it may be still distinctly traced above the subterranean course.

The *Drôme* in Normandy completely loses itself in the midst of a meadow, in a pit of about thirty feet diameter, known to the inhabitants under the name of the *Fosse de Soucy.* But this engulfing takes place only by degrees; for there are other openings in the same locality which, though they are less remarkable, yet, to use the local expression, *drink up* the greatest proportion of its water.

In the same district of France, the *Rille,* the *Iton,* the *Aure,* and other rivers which might be named, are lost by degrees. There are, from one point to another in the beds of these rivers, great gaps, which are called *bétoirs,* and each of which absorbs a portion of the running stream. On its arrival at the bétoir which entirely drinks it up, the stream is usually reduced to the size of a trifling rivulet.

It would be easy to quote examples such as these, in which rivers entirely disappear from the surface. But how much larger a descent of water would require to be taken into account, if well executed investigations had made known to us all the instances in which there was only a partial disappearance? We shall shortly have an opportunity of remarking that the Loire is one of those rivers in which this occurrence may be observed.

There is often in these stratified formations, distinct sheets of water at different depths. The works which have been undertaken in search of coal, near to Saint-Nicolas d'Aliermont, near Dieppe, have proved that there are seven great sheets of water. Their respective positions are as follows:

1st sheet of water at a depth of	76	feet.
2d, - - -	307	do.
3d, - - -	537	do.
4th, - - -	645	do.
5th, - - -	768	do.
6th, - - -	880	do.
7th, - - -	1030	do.

All these collections of water rushed with great force towards the surface.

During the boring of the wells of the Port Saint Ouen, the Messrs. Flachat encountered five very distinct sheets of water, all of which had the tendency to rise.

The 1st at the depth of			108	feet.
2d,	-	-	138	do.
3d,	-	-	156	do.
4th,	-	-	184	do.
5th,	-	-	206	do.

The same engineers encountered four of these reservoirs of water, whilst boring to the depth of 200 feet at Saint Denis, close to the *Place de la Poste aux Chevaux*.

At *Tours*, the three pools, all having a tendency to ascend, which were met with by M. Degousée, were found below *La Place de la Cathedrale*.

The 1st at the depth of			292	feet.
2d,	-	-	240	do.
3d,	-	-	383	do.

The sinking of pits in the neighborhood of London has brought the same truth to light; and the same remark might be made respecting the United States of America.

Negative Artesian Wells.

Sometimes pits are sunk for the purpose of transmitting into the interior of the earth, water, retained at the surface by strata of impermeable clay or stone, and thereby rendering extensive districts mere morasses, unfit for cultivation. The pits by which descend into the interior of the earth those quantities of water which, without this expedient, remain on the surface, may be called *negative artesian wells.* Necessity, the mother of so many important inventions, early suggested to mankind the idea of imitating nature in this point.

The plain of Paluns, near Marseilles, used to be a great morass. It appeared impossible to drain it by the help of the common surface channels. King René, however, caused a great number of pits or drain-wells to be sunk, which are known in the Provençal language by the name of *embugs* (funnels.)* These pits transmitted, and now transmit, in the permeable strata situated at a certain depth, those waters which made the whole country a barren waste. It is positively stated that it is the waters taken down by these embugs of Paluns, which, after a subterranean course, form the projecting fountains of the port of Mion, near to Cassis.

The river Orbe, in the Jura, which descends from the lake of the Rousses, conveys into lake Joux much more water than evaporation removes from it. This latter lake, whence there issues no river, preserves, notwithstanding, a stated elevation which is nearly uniform. "It is," says Saussure, "because nature has provided for these waters subterranean issues, by which they are engulfed and disappear. * * * * As it is of the greatest consequence for the inhabitants of this valley to preserve these natural drains, without which their arable lands and their habitations would be immediately overflowed, they preserve them with the greatest possible care; and when they perceive that they do not take off the water with sufficient velocity, *they themselves open new ones.* For this purpose, all that is necessary is to sink a pit fifteen or twenty feet, having a diameter of about ten feet, in the thin and vertical strata, the summits of which appear on the surface. The name of *entonnoirs* (funnels) is given to these pits." * * * * "It is," adds Saussure, "the waters absorbed by all these entonnoirs, that are observed to rise from the earth, and form a large spring, which is also called Orbe, at the distance of two miles below the southern extremity of the lake." In this passage of two miles, the absorbed waters descend 680 feet.

A manufacturer of potato starch at Villetaneuse, a small village about three miles from St. Denis, in the winter 1832—3, by means of a pit sunk to the depth of certain absorbing stratified beds, got rid of not less than 16,000 gallons of impure water per day, the stench from which had given rise to serious complaints, which probably would have compelled him to give up his establishment. After six months of daily absorption, nothing was found at the bottom of the pit except sand, and this has been uniformly the case from the first.

* It is the property of absorbing, of drinking up the surface waters, possessed by certain natural and artificial openings, which has given the names of *boit-tout*, of *betoirs* or *boitards*, to these drain-wells in certain districts.

From the Farmer and Gardener.

THE CHENOAODIUM QUINOA.

The plant described below, has been successfully cultivated in and near this city by Mr. Gideon B. Smith, since 1829. In 1830 he presented us with a dish of it, and we can bear testimony to its fine qualities. At the instance of Mr. Smith, a lieutenant in our navy procured two bottles of the seed from a farmer in the mountains some distance from Chili. They were procured in the interior at the suggestion of Mr. Smith, because the article as sold in the shops of Peru but rarely germinates, owing to its having been submitted to a process of heating to destroy the egg of an insect of the weevil kind, which is deposited on it. To this cause it is, that we are to ascribe the ill success which has generally attended the attempts to introduce its culture both in Europe and this country. It has been brought here by our sea captains occasionally since about 1805 or 1806; but has rarely if ever vegetated, and was given up by most who tried its cultivation as impracticable: fortunately, however, it fell to the lot of a man who never tires in the pursuit of science—or in his endeavors to add to the comforts of life—to unfold the mystery of its unfruitfulness, and apply the remedy—and to him our countrymen are indebted, for one of the greatest delicacies of the vegetable family which has been introduced among us for many years.

From the Gardener's (English) Magazine.

Humboldt states (as we have quoted in the *Encyc. of Gard.* 2nd edit., §948,) that this plant, in Mexico, ranks in utility with the potato, the maze, and the wheat. The leaves are used as spinach or sorrel, or as greens; and the seeds in soups and broths, or as rice. Throughout a great part of South America, and especially in Peru, the seeds are in as common use as rice is in Hindostan. The seeds are considered more heating than rice, and on that account they are frequently given to domestic poultry to make them lay early. The plant is an annual, and in general appearance resembles the A'triplex hortensis, or French spinach; and, under the same circumstances of soil, climate, &c., will grow to about the same height as that plant. The seeds are small, yellowish white, round, somewhat flattened, about a line in diameter, and, on a cursory glance, might be mistaken for those of millet. Mixed with the latter seeds, and fermented, a pleasant kind of beer is said to be produced. They are contained in a single envelope, from which they are very easily separated. The *Quinóa* was first introduced into England in 1822; and it has ripened seeds at Kew. No particular notice, however, appears to have been taken of the plant till this season, when it has been grown by A. B. Lambert, Esq., V. P. L. S., at Boyton, where it has ripened abundance of seeds on plants varying from three to seven feet in height. These seeds Mr. Lambert will, no doubt, distribute all over Europe; and, we trust, the plant will now have a fair trial both in gardens and fields. To do any good in producing nutritious seeds, the plant should be subjected to field culture, in which we see not the slightest difficulty. It might be sown very thinly in drills, three feet apart, at about the same season as barley, and the plants afterwards thinned to the distance of one foot apart. There appears at present, no reason whatever why it should not become as common in the fields of Europe as barley, wherever that grain can be cultivated. In the meantime, we hope it will be tried first in gardens, in order to raise abundance of seed for future experiments in the field.

From the Richmond Whig.

PROCEEDINGS OF THE JAMES RIVER AND KANAWHA COMPANY.

Tuesday, May 26.

The meeting of the Stockholders of this Company was continued today, agreeably to adjournment, and was more fully attended than on the day previous, but did not, as was expected, go into the election of officers. Mr. Chapman Johnson, from the Committee appointed on the first day, reported the following resolutions prepared by them which he proposed should, for the present, be laid on the table for examination by those who might wish the opportunity—

1. *Resolved,* That of the three plans of improvement specified in the 22d section of the act, entitled "an act incorporating the stockholders of the James River and Kanawha Company," and by one or the other of which, to be selected at its discretion, the company is charged with the duty of connecting the tide-water of James River with the navigable waters of the Ohio, the stockholders deem it expedient and proper to prefer, and do hereby elect, the first in the order of specifications set forth in said selection; that is to say, by a continuation of the lower James River canal to some suitable point on the river, not lower than Lynchburg, a continued rail road from the western termination of that canal to some convenient point on the Great Kanawha River, below the great falls thereof, and an improvement of the Kanawha River from thence to the Ohio, so as to make it suitable for steam boat navigation.

2. *Resolved,* That, with the exceptions hereinafter specified, the canal shall have a breadth at the bottom of not less than 35 feet, and at the surface of not less than 50 feet, and a depth of water of not less than 5 feet, with a suitable tow-path and guard-bank.

3. *Resolved,* That, the breadth of the canal may, within the minimum limit prescribed by the charter, be modified where local circumstances require it; and more especially in the cases of deep cutting, steep side cutting, embanking, and also where it is supported by walls; but a depth of 5 feet shall be preserved throughout the line.

4. *Resolved,* That the locks shall be not less than 85 feet between the gates, and 15 feet wide, and, with the exception of the gates, shall be built of stone; that the culverts shall likewise be made of stone; that the aqueducts shall be erected on stone piers or pillars, surmounted with a superstructure of wood or stone, as may be deemed most advisable; and that the stone work of the locks, culverts and aqueducts, shall be laid in water cement, and executed in a plain, substantial, and durable style of workmanship, admitting the introduction of cut stone only in such parts where it may be deemed indispensable.

5. *Resolved,* That the dams across the river, in connection with the canal, shall be executed in the most substantial and durable style of workmanship; and the location of the number deemed essential in the commencement, shall, as far as practicable, have reference to the introduction of additional intermediate dams, to be erected in future, with a view to a further command of water, and more extended accommodation to the trade from the opposite side of the river.

6. *Resolved,* That in the ponds or pools of water, occupying a portion of the line, the channel and tow-path shall be so adjusted as to admit of the convenient trackage of boats of not less than 75 tons burthen.

7. *Resolved,* That the canal shall be extended to the town of Covington upon Jackson's river, and shall be divided into three divisions: the first commencing at the city of Richmond, and ending at the town of Lynchburg; the second commencing at the town of Lynchburg, and ending at the town of Pattonsburg; and the third commencing at the town of Pattonsburg and ending at the town of Covington.

8. *Resolved,* That the three divisions of the canal shall be executed in successive order; beginning with the first, and proceeding thence to the second; and afterwards from the second to the third; but during the execution of the first and second divisions, preparations may proceed cotemporaneously in the second and third divisions respectively, so that the work may progress without interruption or suspension.

9. *Resolved,* That the whole line of canal within each division thereof, shall be located and put under contract as soon as practicable from the period for its commencement; but the enlargement of the present canal from Richmond to Maiden's Adventure, with a view to adapt it to the rest of the line, and its connection with the head of the tide, may be deferred till the execution of the first divisions shall be advancing to a close.

10. *Resolved,* That the execution of the line of locks and dams on the Kanawha River, shall be referred to the commencement of the execution of the third division of the canal; at which time the works on the Kanawha River shall likewise be commenced; and these works shall progress simultaneously with those on the third division of the canal; so that the line of steam boat navigation on the Kanawha River shall be completed up to the falls thereof, at or about the time that the canal navigation on the James and Jackson's Rivers shall be completed up to the eastern end of the turnpike road at the town of Covington.

11. *Resolved,* That the execution of the rail road from the town of Covington to the falls of Kanawha, shall be deferred until after the execution of the water parts of the line.

12. *Resolved,* That the execution of the line of improvement shall be commenced as soon as practicable, by the commencement of the first division of the canal, and continued in the manner and orded prescribed, till otherwise directed by the stockholders.

13. *Resolved,* That until the further order of the

stockholders, the plan of the canal and of the rest of the works, in points not heretofore enumerated, or not fully explained, shall, along with their execution, be confided to the charge and discretion of the President and Directors of the Company.

The adoption of the resolutions was opposed at some length by Messrs. Philip Norborne Nicholas and Wyndham Robertson. It was obviously of the utmost importance that the most judicious of the different modes of effecting the improvement in view, authorised by the charter, should be adopted before it should be commenced; as an error in the outset could not be remedied but at an immense expense. But the question, whether the canal or rail road system of improvement, generally, was preferable, was one on which the most distinguished engineers differed; and the like diversity of opinion as to whether the present work should be by rail road, wholly, or by canal, so far as practicable, obtained among the engineers, who had applied their minds to this particular subject. It was impossible, therefore, they contended, that the stockholders, to many of whom the question had never before been presented, could, at this time, come to a judicious decision; and they preferred that the company should first of all be organized by the appointment of officers, whose duty it should be to collect the best information, and digest a plan, to be laid before the stockholders, for acceptance, at some future meeting. Mr. Robertson concluded his remarks by offering the following resolutions, as a substitute for those presented by the committee:

Resolved, That the President and Directors of the James River and Kanawha Company, proceed as early as may be practicable, to examine and consider the question of the most eligible mode of improvement authorized by the charter, for the country between the city of Richmond, and such point as said President and Directors may deem most suitable for the head of canal navigation, keeping in view the great ends proposed to be attained by the work contemplated, viz: public accommodation and the profits of the stockholders.

That should the examination of the various reports, surveys, profiles, and estimates heretofore made in reference to the improvement of the communication between the points indicated, and now the property of this company, and of all such other data, as they may be able to command, not enable the said President and Directors to arrive at a conclusion satisfactory to themselves of the question proposed for their consideration, or should they for any cause deem it advisable, the said President and Directors shall be at liberty to call to their aid one or more civil engineers, the most eminent to be procured, to perform such services as said President and Directors, may require; the expense thereby incurred to be defrayed out of the funds of the company.

That having thus duly possessed themselves of all the information within their reach calculated to shed light on this interesting inquiry, and duly weighed the same, it shall be the further duty of said President and Directors to digest the same into the form of a report, wherein they shall present, as fully and fairly as they can, all the considerations that recommend or forbid the adoption of each of the alternative modes of improvement authorized by the charter, together with the conclusions to which, on a view of the whole ground, they shall themselves have arrived.

That the said President and Directors cause copies of said report to be printed in pamphlet form, as soon as the same shall have been prepared, and take such means as to them may seem best for transmitting one copy thereof to each stockholder in said company.

That the said President and Directors call a general meeting of the stockholders of said company within days after the publication of said report, to take said report into consideration.

Some discussion followed between Messrs. Joseph James, Chapman Johnson, Sidney S. Baxter, David I. Burr, and Fleming James; in the course of which a general call was made for the reasons of the committee for the resolutions which they had presented.

The call was responded to by Mr. Joseph C. Cabell, who gave a brief history of the rise and progress of the project about to be put in execution, from its inception in 1810 to the present time, adverting to the various surveys, reports, and discussions had upon the very subject during that period, and contending that in these several ways ample opportunity had been given to all who felt interested in the matter, to acquire the requisite knowledge in reference to it. He referred also to various investigations of the relative merits of the canal and rail road systems, which had taken place in other states—the result of all which, as well as the surveys, reports and discussions above alluded to, was in his opinion, conclusive in favor of the system selected by the committee. In addition to this weight of authority, he professed himself ready to go into the discussion of the question on its own merits; but owing to the lateness of the hour, contented himself with citing a summary of the arguments of Mr. Mercer in his report to congress in 1832, and with stating the following "objections to the substitution of a continuous rail road for a canal in the valley of the James and Jackson Rivers:"

1. That the preference of a continuous rail road will cause the loss of nearly the whole amount of capital invested in the lower James River canal, and the canal at the Blue Ridge.
2. Transportation would be more expensive, in the proportion of at least two to one.
3. It would be the means of exchanging a free highway for a close monopoly.
4. The property transported would be more exposed to damage.
5. Transportation on rail roads is inconvenient for many heavy articles.
6. The adoption of a continuous rail road would cause the loss of the water power of the rivers connected with a canal, and of the valuable estate held by the company in the waters of the rivers, as well as of the manufactories, towns and villages, to result from the water power to the community at large.
7. That a continuous rail road would be more exposed to the danger of competition in the vicinity and at a distance.
8. That the two species of improvement possess each its peculiar advantages, neither possessing all the advantages of the other, and both being necessary *ultimately* to the prosperity of the central line; and that the adoption of a continuous rail road would preclude a canal, whilst the adoption of a canal would not necessarily preclude a rail road.

The discussion was continued a short time further by Messrs. Nicholas, Burr and Carter Harrison, when the resolutions and substitute were laid on the table and ordered to be printed; and the meeting adjourned till 12 o'clock to-morrow.

Wednesday, May 27.

On Wednesday evening, after a recess, the stockholders again convened, when the discussion of the committee's resolutions and Mr. W. Robertson's substitute was resumed, and continued by Mr. C. Johnson for the former, and Messrs. J. James, P. N. Nicholas, J. B. Harvie, and W. Robertson, until about 8 o'clock. The question on the adoption of the substitute was then put, and being regarded as a test question, the ayes and noes, according to the stock represented, were ordered; and the same being called, the substitute was rejected, ayes 450, noes 6820—including the vote of the state, and of the corporations of Richmond, Lynchburg and the Bank of Virginia.

The first six resolutions reported by the committee were then taken up in succession, and after a few remarks by Mr. J. C. Cabell in support of each, were adopted by a *viva voce* vote. The first of these, it will be recollected, adopts the plan of continuing the James River canal to some point on the river, not lower than Lynchburg; constructing a rail road from thence to some point on the Great Kanawha River, and improving the navigation of the Kanawha from thence to the Ohio. The others regard the dimensions, and mode of constructing the canal, locks, &c.

On the reading of the seventh resolution which provides that the canal shall be extended to Covington, and be divided into three sections—the first extending from Richmond to Lynchburg, the second from Lynchburg to Pattonsburg, and the third from Pattonsburg to Covington—Mr. John Robertson opposed its adoption, on the ground that it was inexpedient for the stockholders to commit themselves, at this time, to the continuation of the work by canal, in preference to a rail road, west of Lynchburg, inasmuch as it was obvious that that part of the improvement could not be undertaken until a year or two hence, when the experience acquired during the construction of the canal to that point, with other future contingencies, might incline the company to substitute the rail road system from thence to Covington. After some discussion on this point, principally between Messrs. J. Robertson and J. C. Cabell, the subject was laid on the table, and at half after nine the meeting adjourned till 10 o'clock yesterday morning, [28.]

Yesterday, agreeably to adjournment, the meeting convened, when Mr. J. Robertson proposed the following, as a substitute for the seventh resolution of the committee, viz:

Resolved, That it is expedient to continue the Lower James River canal to the town of Lynchburg, and that the line of the said improvement should be located and put under contract with all practicable despatch.

Resolved, That it is unnecessary and inexpedient, at this time, to prescribe any specific plan for the residue of the work authorized by the charter of the company for connecting the eastern and western waters.

Resolved, That the President and Directors of the James River and Kanawha Company, proceed, without delay, to consider the different modes of improvement which may be proposed, or which may suggest themselves to their minds as worthy of examination, for the residue of the work, calling to their aid one or more able engineers, and report to the stockholders, at their next stated or regular meeting, the plan deemed by them most eligible for the said improvement, with a full and detailed statement of the reasons and considerations which may have recommended such plan to their adoption.

These resolutions were supported by Messrs. J. Robertson, P. N. Nicholas, and J. B. Harvie, and opposed by Mr. J. C. Cabell, in a debate of some length. Finally, on vote taken, they were rejected. The seventh resolution of the committee was then adopted.

On the reading of the eighth resolution, prescribing the order in which the three divisions of the canal shall be executed, Mr. J. B. Scott, proposed the following by way of substitute.

Resolved, That the execution of the work shall commence at the town of Covington, on Jackson's River, and be prosecuted eastwardly to the town of Lynchburg, and thence to the city of Richmond; and that contracts for the construction of the rail road from the town of Covington to the falls of Kanawha, shall be made simultaneously with the commencement of the other part of the work.

After a discussion of considerable length, in which the substitute was supported by Mr. Scott and opposed by Messrs. Chapman Johnson and James Lyons, it was rejected. Thereupon, the 8th, and the remainder of the resolutions reported by the committee, were adopted.

Mr. C. Johnson from the committee, then reported a series of by-laws for the regulation of the company, which were laid on the table, and the meeting agreed to a recess until five o'clock, P. M.

On Thursday evening, after a recess, the meeting re-assembled. The by-laws, reported by the committee, having been amended, were adopted. The meeting then proceeded to elect the following officers:

Joseph C. Cabell of Nelson, President, (unanimously elected.)

Directors:
Sidney S. Baxter of Richmond City,
Samuel Mark of Richmond City,
Richard Sampson of Goochland,
Randolph Harrison, sen. of Cumberland,
John H. Cocke, Sen. of Fluvanna,
John Early of Lynchburg, and
Hugh Caperton of Monroe,

The Chairman having delivered the several books and documents, lying on the table, into the hands of the President elect of the company, the meeting adjourned, *sine die*.

PRINCIPLES OF BREEDING. MANAGEMENT OF MARES AND THEIR FOALS.

This may be a proper period to recur to the important subject of breeding, particularly important when there cannot be a doubt that our breed of useful horses has, within the last twenty years, most materially degenerated. Our running-horses are not much lessened in excellence and value; but our hunters and hackneys are not what they used to be. We shall endeavor to point out the cause of this.

Our observations must be of a general nature, and will be very simple; and the first axiom we would lay down is, that "like will produce like," that the progeny will inherit the qualities, or the mingled qualities, of the parents. We would refer to the subject of diseases, and again state our perfect conviction, that there is scarcely one by which either of the parents is affected, that the foal will not inherit, or, at least, the predisposition to it: even the consequences of ill usage or hard work will descend to the progeny. We have already enlarged on this, but its importance will be a sufficient apology for the repetition. We have had proof upon proof, that blindness, roaring, thick wind, broken wind, spavins, curbs, ringbones, and founder, have been bequeathed, both by the sire and the dam, to the offspring. It should likewise be recollected, that although these blemishes may not appear in the immediate progeny, they frequently will in the next generation. Hence the necessity of some knowledge of the parentage both of the sire and dam.

Peculiarity of form and constitution will also be inherited. This is a most important, but neglected consideration; for however desirable, or even perfect, may have been the conformation of the sire, every good point may be neutralized or lost by the defective form, or want of blood, of the mare. There are niceties in this, of which some breeders used to be aware, and they employed their knowledge to great advantage. When they were careful that the essential points should be good in both parents, and that some minor defect in either should be met, and got rid of, by excellence in that particular point in the other, the result was creditable to their judgement, and highly profitable. The unskilful or careless breeder will often so badly pair the animals, that the good points of each will be, in a manner, lost: the defects of both will be increased, and the produce will be far inferior to both sire and dam.

Of late years, these principles have been much lost sight of in the breeding of horses for general use; and the following is the explanation of it. There are nearly as good stallions as there used to be. Few but well formed and valuable horses will be selected and retained as stallions. They are always the very prime of the breed; but the mares are not what they used to be. Poverty has induced many of the breeders to part with the mares from which they used to raise their stock, and which were worth their weight in gold; and the jade on which the farmer now rides to market, or which he uses in his farm, costs him but little money, and is only retained because he could not get much money for her. It has likewise become the fashion for gentlemen to ride mares, almost as frequently as geldings; and thus the better kind are taken from the breeding service, until old age or injury renders them worth little for it. An intelligent veterinary surgeon, Mr. Castley, has placed this in a very strong light, in the third volume of the "Veterinarian," p. 371.

We would wish, then, to impress it on the minds of breeders, that peculiarity of form and constitution are inherited from both parents; that the excellence of the mare is a point of quite as much importance as that of the horse; and that out of a sorry mare, let the horse be as perfect as he may, a good foal will rarely be produced. All this is recognised upon the turf, although poverty or carelessness have made the general breeder neglect or forget it.

It is recognised in the midland counties in the breed of cart horses; and the strict attention which has been paid to it, has brought our heavy horses to almost the same perfection in their way as the blood-horse. It is strange that in our saddle-horses, our hunters, and, to a great degree, our carriage-horses, this should be left to chance. The breeder begins to care little about the quality of the mare, and the progeny is becoming comparatively of little worth. Experience, it is said, will make fools wise, but experience will here be bought at a very dear rate, both as it regards the breeder and the community.

That the constitution and endurance of the horse are inherited, no sporting man ever doubted. The qualities of the sire or the dam descend from generation to generation, and the excellencies or defects of certain horses are traced, and justly so, to some peculiarity in a far distant ancestor.

It may, perhaps, be justly affirmed, that there is more difficulty in selecting a good mare to breed from, than a good horse, because she should possess somewhat opposite qualities. Her carcass should be long, to give room for the growth of the fœtus, and yet with this there should be compactness of form and shortness of leg. What can they expect who go to Smithfield market to purchase a number of worn-out, spavined, foundered mares, about whom they fancy there have been some good points, and send them far into the country to breed from, and, with all their variety of shape, to be covered by the same horse? In a lottery like this, there may be now and then a prize, but there must be many blanks. "If horse-breeders, possessed of good judgement, would pay the same attention to breed and shape as Mr. Bakewell did with sheep, they would probably attain their wishes in an equal degree, and greatly to their advantage, whether for the collar or the road, for racing or for hunting."*

As to the shape of the stallion, little satisfactory can be said. It must depend on that of the mare, and the kind of horse wished to be bred; but if there be one point which we should say is absolutely essential, it is this, "compactness"—as much goodness and strength as possible condensed in a little space. If we are describing the reverse of the common race of stallions for hunters and coach-horses, the fault lies with the bad taste and judgement of the majority of breeders.

Next to compactness, the inclination of the shoulder will be regarded. A huge stallion, with upright shoulders, never got a capital hunter or hackney. From him the breeder can obtain nothing but a cart or dray-horse, and that, perhaps, spoiled by the opposite form of the mare. On the other hand, an upright shoulder is desirable, if not absolutely necessary, when a mere draught horse is required.

It is of no little importance, that the parents should be in full possession of their natural strength and powers. It is a common error, that because a mare has once been good, she is fit for breeding when she is no longer capable of ordinary work. Her blood and perfect frame may ensure a foal of some value, but he will inherit a portion of the worn-out constitution of her from whom he sprung.

On the subject of *breeding in and in*, that is, persevering in the same breed, and selecting the best on either side, much has been said. The system of crossing requires much judgement and experience; a great deal more, indeed, than breed-

* Parkinson on the Breeding and Management of Live Stock, vol. ii. p. 59.

ers usually possess. The bad qualities of the cross are too soon engrafted on the original stock, and once engrafted there, are not, for many generations, eradicated. The good ones of both are occasionally neutralized to a most mortifying degree. On the other hand, it is the fact, however some may deny it, that strict confinement to one breed, however valuable or perfect, produces gradual deterioration. The truth here, as in many other cases, lies in the middle; crossing should be attempted with great caution, and the most perfect of the same breed should be selected, but varied, by being frequently taken from different stocks. This is the secret of the course. The pure south-eastern blood is never left, but the stock is often changed with manifest advantage.

A mare is capable of breeding at three or four years old; some have injudiciously commenced at two years, before her form or her strength is sufficiently developed, and with the developement of which this early breeding will materially interfere. If she does little more than farm-work, she may continue to be bred from until she is nearly twenty; but if she has been hardly worked, and bears the marks of it, let her have been what she will in her youth, she will deceive the expectations of the breeder in her old age.

The mare comes into heat in the early part of the spring. She is said to go with foal eleven months, but there is sometimes a strange irregularity about this. Some have been known to foal five weeks earlier, while the time of others has been extended six weeks beyond the eleven months. We may, however, take eleven months as the average time. In running horses, that are brought so early to the starting-post, and whether they are foaled early in January or late in April, rank as of the same age, it is of importance that the mare should go to cover as early as possible: in a two or three year old, four months would make considerable difference in the growth and strength; yet many of these early foals are almost worthless, because they have been deprived of that additional nutriment which nature designed for them. For other breeds, the beginning of May is the most convenient period. The mare would then foal in the early part of April, when there would begin to be sufficient food for her and her colt, without confining them to the stable.

From the time of covering to that of foaling, the mare may be kept at moderate work, and that not only without injury, but with decided advantage. The work may be continued up to the very time when she is expected to foal; and of which she will give at least a day's notice, by the adhesive matter that will appear about the teats. When this is seen, it will be prudent to release her from work, and keep her near home, and under the frequent inspection of some careful person.

When nearly half the time of pregnancy has elapsed, the mare should have a little better food. She should be allowed one or two feeds of corn in the day. This is about the period when they are accustomed to slink their foals, or when abortion occurs: at this time, therefore, the eye of the owner should be frequently upon them. Good feeding and moderate exercise will be the best preventives against this. The mare that has once slinked her foal is ever liable to the same accident, and therefore should never be suffered to be with other mares about the time that this usually occurs, which is between the fourth and fifth months; for such is the power of imagination or of sympathy in the mare, that if one of them suffers abortion, the greater number of those in the same pasture will share the same fate. Farmers wash, and paint, and tar their stables to prevent some supposed infection:—the infection lies in the imagination.

If a mare has been regularly exercised, and apparently in health while she was in foal, little danger will attend the act of parturition. If there be false presentation of the fœtus, or difficulty in producing it, it will be better to have recourse to a well informed practitioner, rather than injure the mother by the violent, and injurious attempts which are often made to relieve the animal.

As soon as the mare has foaled, she should be turned into some well sheltered pasture, with a hovel or shed to run into when she pleases: and as supposing she has foaled in April, the grass is scanty, she should have a couple of feeds of corn daily. The breeder may depend upon it, that nothing is gained by starving the mother and stinting the foal at this time. It is the most important time in the life of the horse; and if, from false economy, his growth be arrested now, his puny form and want of endurance will ever afterwards testify the error that has been committed. The corn should be given in a trough on the ground, that the foal may partake of it with the mother. When the new grass is flush and plenty, the corn may be gradually discontinued.

Our work is intended, principally, for farmers: they well know that the mare may be put to moderate work again a month after the foaling. The foal is at first shut in the stable during the hours of work; but as soon as it acquires sufficient strength to toddle after the mare, and especially when she is at slow work, it will be better for the foal and the dam that they should be together. The work will contribute to the health of the mother; the foal will more frequently draw the milk, and thrive better; and will be hardy and tractable, and gradually familiarized with the objects among which it is afterwards to live. While the mother, however, is thus worked, she and the foal should be well fed; and two feeds of corn, at least, should be added to the green food which they get when turned out after their work, and at night. The mare will usually be found at heat at or before the expiration of a month from the time of foaling, when, if she be kept principally for breeding purposes, she may be put again to the horse.

In five or six months, according to the growth of the foal, it may be weaned. It should then be housed for three weeks or a month, or turned into some distant rick-yard. There can be no better place for the foal than the latter, as affording, and that without trouble, both food and shelter. The mother should be put to harder work, and have drier meat. One or two urine balls, or a physic ball, will be useful if the milk should be troublesome, or she should pine after her foal.

There is no principle of greater importance than the liberal feeding of the foal during the whole of his growth, and at this time in particular. Bruised oats and bran should form a considerable part of his daily provender. The farmer may be assured that money is well laid out which is expended on the liberal nourishment of the growing colt: while, however, he is well fed, he should not be rendered delicate by excess of care. A racing colt is sometimes stabled; but one that is destined to be a hunter, a hackney, or an agricultural horse, should merely have a square rick, under the leeward side of which he may shelter himself, or a hovel, into which he may run at night, or out of the rain. The process of breaking-in should commence from the very period of weaning. The foal should be daily handled, partially dressed, accustomed to the halter, led about, and even tied up. The tractability, and good temper, and value of the horse, depend a great deal more upon this than breeders are aware: this should be done as much as possible by the man by whom they are fed, and whose management of them should be always kind and gentle. There is no fault for which a breeder should so invariably discharge his servant as cruelty, or even harshness, towards the rising stock; for the principle on which their after usefulness is founded, is early attachment to, and confidence in man, and obedience, implicit obedience, resulting principally from these.

From the National Intelligencer.

SUBMARINE ARCHITECTURE—ALEXANDRIA AQUEDUCT.

We have never had an opportunity of inspecting a more remarkable triumph of art than the operation of building massy stone piers in the bed of the River Potomac, now going on near Georgetown, at the expense of the Alexandria Canal Company, under the direction of Capt. Turnbull, of the U. S. Topographical Engineers. We yesterday paid a visit to the work, and found it to surpass our previous conception of it, as well in regard to the magnitude of the enterprise, as to the ingenuity with which very formidable obstacles have been overcome. These piers, the reader must understand, are to support an aqueduct, or canal, being a branch of the Chesapeake and Ohio Canal, which is to cross the river in this manner on its way to Alexandria. It is truly a stupendous undertaking, with no parallel in this country, and, we believe, scarcely equalled in any other. The pier which is begun is the second from the Alexandria (or Virginia) shore; the first being the next to be built. The foundation of this pier is on the bare rock, and the structure is of solid masonry, formed of very large blocks of excellent stone from the falls' quarries, skillfully laid in water cement. To accomplish the object, a vast coffer dam has been constructed, the interior of which is about eighty feet long and nearly thirty wide. The depth of water to be shut out by this dam is 18 feet, and the depth of mud below that depth of water, which mud it was necessary also to remove, was more than 17 feet; so that the building was begun at a depth of thirty seven feet below the surface of the water. Notwithstanding which, so successful had been the preparations for resisting the vast external pressure of water, that the rocky bottom was laid bare the whole extent of the area, enclosed and even swept clean and dry with brooms, before the cement was applied, in which, a few days ago, the first course of stone was laid. The length of the pier now building is, at the base, sixty-six feet, running in its length with the current and the tide; its precise breadth we do not remember, but it must be something over 15 feet. The mason work of the pier is going on rapidly and successfully. It had yesterday reached above 10 feet in height from the bottom. The whole number of these piers (some of them even larger than this) is to be eight, besides the end piers or abutments, and upon these the canal is to be carried, at an elevation of thirty feet above the level of the river.

We have given this sketch of a very remarkable work, in our immediate vicinity, first, because it is remarkable; secondly, to express our admiration of the spirit of the town of Alexandria in persevering in this undertaking of her's in defiance of all obstacles; and thirdly, that we may give the credit due to the accomplished engineer, who had labored so untiringly in carrying on this operation, and has now the gratification of rejoicing in its success. He is ably assisted in this duty at present by Lieut Ewing of the artillery, now on Topographical duty.

[The following letters, though treating on several different subjects, are all in some degree connected with each other, and with two others which have been already published—one "On the cultivation of corn mixed with other crops," at page 634 of Vol. II, and the other in last No. page 62, "On making rice on dry lands," These and the previous statements of the *profitable* application of so much labor and care for the purpose of making manure and improving the soil, are the more deserving of attention, because proceeding from the rich and new lands of Alabama, where (as in all similar situations,) it is generally held to be useless to expend any labor, either to increase or preserve fertility—or for any other purpose indeed, except to make as heavy a crop as possible in the current year, without regard to future consequences.]

For the Farmers' Register.

RICE BREAD—ON CORN MIXED WITH OTHER CROPS, CONTINUED.

Discovering from your letter of the 15th February, that cultivating rice on dry land was new to you, I have thought that one of the ways in which we use it, may be so equally. This mode of preparing it, grows with us out of the circumstance of raising it ourselves, with much ease, and having it in plenty. This grain is made to add to our bread stuffs, and is found a most superior addition. It is sent to the mill in its rough state, ground as wheat, and bolted, or returned to be passed, as corn meal, through the fine sieve. The flour is put through the usual process of making wheat bread, and made into loaves, in the form of what is termed "*family bread.*" When baked, it is as light and spongy as a fine muffin—and when accompanied by good butter, cannot be surpassed, in my opinion, by any preparation of the bread kind. Like the corn, it requires to be used in a warm state. When cold, it becomes unfit for use totally. But here again, domestic economy has contrived a valuable appropriation of what becomes cold, or is left after meals. Thrown into a pot with clean water the next day, it dissolves as soon as the water arrives at the boiling point, and if a fat fowl is added, makes, with the usual additional items, a superb soup. The absolutely necessary point in the fabrication of this bread is to have it light. This the Indians effect, who make it well, by making up the bread, or dough, entirely with hot water, in which the grits, as they call it, have been steeped, and which appears to act as an yeast in producing lightness. I have frequently used the hop yeast with equal success, although I prefer the Indian mode. As a breakfast preparation, this bread with good butter, if the first is well made, may fairly be termed a luxury. The first time I saw it its excellence surprised me, exhibiting a preparation to me entirely new, and unthought of—at the same time prepared with so much ease. The loaf may be made large. That a change of bread, as well as other articles of diet, is essential in preserving a healty action and tone of the digestive organs, I believe is well determined; consequently, rice bread, which must evidently be one of the most salutary, may fairly be enlisted in the number.

A sheaf of this grain submitted to the cutting box, and sprinkled with a small quantity of rye or Indian corn meal, is thought by our best horse masters to have a happy effect on the stomach of that useful animal—given at least weekly.

If my mode of cultivating land is the productive one,* it will be discovered readily that the manner in which I save my corn crop is what secures it, as but for the adoption of that plan, it would be out of the question. If to produce the greatest result possible, from any given quantity of land, and labor bestowed on it, is the course that a judicious cultivation of land would demand, and that it is, I believe may be termed a self-evident proposition, then the mode of cultivating land which I suggest, must be the correct one. Is it not making the "two stalks stand where but one stood before?" But still it must be observed, that the manuring plan comes in for a full share. Then the wisdom of that plan is equally self-evident, as but for it also, the result could not be obtained. But give the manure, and cut down and remove the corn when at maturity, and the result is certain.

The remarks of that distinguished cultivator Judge Buel, on this subject, in his excellent paper on the cultivation of the corn crop, must be familiar to reading agriculturists. There, it will be recollected, the Judge contends against any loss in the corn by this mode of saving the crop. So do I—and so will all who will fairly and judiciously try it. But if there should be a little shrinkage in the corn, there is none in the potatoes—the rice—the peas, and the pindars, [ground peas.] I ween two hundred bushels per acre of those valuable productions, will amply settle the shrinkage account, as also fairly and fully close that opened for "trouble." Nor will it be deemed, I hope, a small item in the adjustment of "profit and loss," that my land is well shaded by valuable ameliorating crops, during that part of the season when the burning rays of the sun acts so powerfully on land. The success of corn after rice, on upland, with us, it proverbial—especially if the stubble is turned well under. The effect of the potato, the pea, and the pindar on land, is well known, as improvers of soil. To those who are disposed to enter into the calculation, and adjust the account fairly, I will remark, that the manuring I give, preparatory to this "heavy crop," is an insurance for three more, or rather *five more in three years*—my rotation being corn, &c. cotton, rye, and peas on the stubble ploughed in, oats and peas on its stubble, followed by grass one year—no pasturing. The grass year is intended as a year of perfect rest to the land.

*See account of the cultivation at p. 634, vol. II.—Ed.

But to form a correct estimate of the value of my plan of saving the corn crop in addition to what has been already stated, I must beg leave to refer you to an accompanying paper on saving corn-stalks and converting them into a superior food, where it will be seen that I derive from my corn crop, a most valuable resource for raising cattle, and that the plan I have adopted for saving my corn gives me all the "refuse" of the corn in that state in which it yields the greatest possible quantity of nutriment, consistent with making the grain —and that this refuse part amounts to a prodigious mass to the acre—as also the pea crop in the manner in which I cure and preserve the vines—as also the vines of the potato crop, and pindars.

You will readily conceive that my corn field after the whole production is housed, enables me to support amply, a large stock. A principal feature in my theory is, to maintain and keep every hoof that I can support well, and of course to turn to the account of forage, every thing that can be made to go it. With me the key stone to the arch is, *manure*—but the year after I manure, I never fail to lime—the last slaked. I am aware the question will be asked, what do I litter with? To this I will say, leaves and weeds—and I litter well. My cattle lie dry and warm in winter—in summer dry and cool, on beds of leaves and weeds, and my fence rows are kept clean. Every thing that can be eaten by my stock is eaten, because it is prepared for that purpose: and my stock in return, gives that which prepares the leaves and weeds for giving to the soil additional productive powers, and secures the heavy crop, and ample remuneration for the labor bestowed.

ON SAVING CORN-STALKS, AND PREPARING THEM AS FOOD FOR CATTLE.

In my paper of the 25th March I referred to another on the subject of the plan of saving a corn crop adopted by me, in such a manner as to reap from every part of the refuse a great benefit in the way of feeding my cattle. The appropriation of the stalk particularly, in this way, so as to make it yield the greatest benefit that could be obtained from it, consistent with producing and saving the crop of grain, early arrested my attention, from reading a variety of communications for years back on the subject of the nutritive qualities contained in the stalk at particular periods—as also some experiments made in feeding with them. In the prosecution of this object, I was urged by succeeding in saving a corn crop in the manner pointed out by that valuable agriculturalist Judge Buel, and which plan I had seen practised on the South Branch of Potomac, before reading it. I make this communication to you, sir, the more especially, as I have read in your highly valuable periodical, the "Register," some communications on managing the corn-stalk to advantage, and believing that I am considerably ahead in an economical use of it. Since the plan has been adopted by me, and its valuable effects exhibited, you will be assured I read with some pain the many labored communications so frequently given to the public, of judicious methods of turning the corn-stalk into manure, &c. The prodigious mass of valuable food produced from a field is another consideration that I am compelled to regard with much interest. All will readily acknowledge that at one stage the corn-stalk as a food for animals, exhibits highly nutritious qualities. Now to arrest, or save as much of those in it as possible, is one of the great arguments with me, in favor of my mode of saving the corn crop; but I am assured this is equally effected as regards the fodder and shuck.

After housing my corn crop, as before stated, [p. 635, Vol. II.] the first rainy day, if no more pressing wet work is calling for attention, all hands "go to shucking corn, and stripping off blades." If I am in want of this last species of forage for my plough horses, or mules, which by the by is not often the case, as my gama grass hay and oats cut in the sheaf with which the cutting trough is kept constantly replenished, supplies that want. In shucking the individual throws the corn in one direction, and lays the stalk with attention to regularity beside him, until he has an armfull, when he takes them up carefully, and deposites them a short distance from him, in regular order for putting into the cutting box, where they are reduced, frequently stalk, shuck, and blade, to pieces of about an inch in length.

At a convenient distance from this apartment, three strong made hogsheads are placed, well pitched on the outside, made expressly for the purpose, with tops well fitted of light wood or straw, and standing on a platform about three feet from the ground, having at the bottom a large spigot to let off their contents. Just before them a large trough is placed, and which, with the steaming apparatus standing between the two last, is inclosed and covered with a shed. Into these hogsheads I throw a small quantity of boiling water, and into the water a small quantity of corn or rye meal, just sufficient, when the cask is filled up with cool soft water, to produce the vinous fermentation, as if going to distil. As soon as the liquid has attained that state, I steam off a turn of the cut stalks, shucks, &c., putting the last into the trough, over which, by means of a portable trough, such as distillers use, I permit the fermented liquid to flow and cover the cut stuff, which has been well pressed down previously in the trough, and held down by a moveable top. This done in the evening, the forage becomes perfectly saturated by morning with the liquid, at once one of the most nutritious and palatable preparations for the cow kind yet discovered. The cut stuff charged with the wash, is deposited in the feeding troughs, taken out of the trough in which they are saturated, in baskets, which carries away no more of the liquid than what is contained in it by absorption. Every particle is consumed by the cattle, care being taken to serve them with the food as they consume it. By a little arrangement I keep my hogsheads so filled, that one is always ready for use. My horses and mules consume this preparation with equal *gout* as the cattle. As a food for my work oxen when laboring, it is, experience convinces me, superior. It "sticks by the ribs"—and plentifully given keeps them in fine plight. The apparent pleasure with which the animals consume this preparation is observable. I know of no food which they eat with more avidity—and what I consider of much advantage to them, especially the cow kind, they soon fill themselves. Satisfied that nature intended that the food of animals should include a variety, and that this being a law of nature, this variety is necessary for the highest state of animal health, I have added to the stalks every vegetable substance that can be subjected to the cutting box, usually given as food, viz: straw of oats, rye, rice, wheat and hay, pea vines, and sweet potato vines cured—and if plenty, any vegetable roots that can be spared from other animals—and in the season, a portion of grass. I am fully satisfied that the gain in keeping my cattle, which I obtain from cutting up their food, is much more than an equivalent for the time and labor bestowed—and that a still greater equivalent is received from the steaming; for it must be remembered, I convert into food a mass of what could not otherwise be made so.

My first essay was with the stalk alone, stripped of blades and shuck. The result was about the same as when the blades and shuck were permitted to go to the trough. The effect produced by this preparation, on milch cows, I have found all that could be desired—and in addition to the foregoing, with plenty of salt, it will be found to produce in the animals a high degree of health.

Now, sir, in answer to some of your excellent correspondents, I will observe that I am compelled to view my plan as the best to convert the corn-stalk into manure: and I view my gain on this score, equally great. My cattle are well littered with pine straw, or oak leaves, &c. The production of my corn-stalks passing through the stomach of animals, affords me the rich means of converting them into the best of manure, to a prodigious amount. Here my gain over the ploughing-in system is, I think, decided and self-evident. Plough in a ton of stalks, and let me carry out of my dungstead what another ton has enabled me to produce, and the result will readily be anticipated.

AGRICOLA.

Alabama, March 30, 1835.

For the Farmers' Register.

THE PEA AND POTATO HARVEST, ON THE PLAN OF MIXED CROPS.

My last paper finished the saving of my corn stalks, and their conversion into food for cattle, in a way that I have found highly profitable. The pea and potato vines remain to be disposed of. As early as the pea will admit of curing by pulling up, and exposing to the sun and wind, I proceed selecting weather that offers some apparent security for a few days of clear sky. I pull them up, shaking as much earth from the roots as conveniently can be detached, raise the vines partly from the ground, and turn them partially over, so that they may stand up from the earth as much as possible. In all the different peas I cultivate, I find that my plan in saving this part of the crop, enables me to secure every leaf almost green. I do not fear a little shrinkage in the pea, more than the corn, as the ultimate gain meets that charge. After two days sun, and as many turnings over, and raising from the ground, they are carried home, and in a pen built of common rails, (a few armfulls of dry straw laid in the bottom, which is a tight floor,) I throw the pea vines, which are pressed down by the weight of children, into a layer of about twelve inches thick—over this layer I scatter a few handfuls of fine salt, not being careful about giving too much, as there will be none lost ultimately; whatever goes to the bottom will be arrested by the floor, and answer the next season for cattle. A few handfuls of dry straw are again added, sufficient to separate the layers of pea vines; then pea vines, salt and straw, until my pen is full. On commencing to fill my pen, I place a keg in the centre, which is drawn up as I progress, so that when the pen is filled, a hole is formed in the centre, admitting the escape of gas, and the entrance of atmospheric air. Over the whole I now place a tight roof of clap-boards, securing their remaining as placed in the usual manner. I will leave to your readers to *guess*, as they would have to do were they in Connecticut, at the reason, but the straw used in this process of saving pea vines, is eaten with singular avidity by all kinds of stock, as it is taken from amongst the peas. For sheep, this kind of winter provision cannot be excelled—given to milch cows, its valuable effects is soon discovered on the flesh, milk, and butter. It is also excellent for producing a fat kid. Any peas dropped by the cattle or sheep, are well accounted for by the pigs—nothing is lost. The pindar vines are disposed of in the same way—and the vines of my sweet potato crop, of which I make the richest of forage for cattle.

About the time of digging my potato crop, with a proper reference to the weather, by the aid of the common sickle, or a knife constructed for this purpose, I cut the vine from the hill or ridge, drawing them partially together, for the purpose of raising them as much as possible from the ground to admit the action of the sun's rays, and the operation of drying winds. On the succeeding day, I turn them partially over, and repeat the same on the third; hauling them home on the fourth, to dispose of them in the manner before stated, respecting preserving the pea vines. In the article of salt to the potato vines, a little more liberality is bestowed, and they are pressed down in the pen only by their own weight, observing to lay them as regular in the layers as possible. This offal, when cut and steamed for milch cows, is certainly superior.

The frequent difficulty of saving those two crops of offal, by a sudden change of wet weather, must be acknowledged: I have found, however, that the cure is redoubled activity—if a heavy shower only takes place, neither the one nor the other is gone—raised up and turned over a little more frequently, and the effect of one wetting is soon got clear of. If the misfortune of a wet season happens, I haul home, bring up every thing that will eat vines, and feed away under sheds, in my stables and dungstead—keeping up my stock, principally, until all is consumed: consequently, I save in the manure account.

My potatoes I dig and haul home, saving in the usual way. In my former statements respecting this part of the crop, I find myself guilty of an omission that would induce a reader to ask where I got a sufficiency of seed to plant a large field? I lay off the part of the field to be planted in potatoes, find how much seed I have, and how far it will go—plant every third, fourth, fifth or sixth row of corn hills, as the case may make necessary. As the potatoes throw out vines, I cut them, and plant the slips so obtained until my field is filled out. The balance of the potato crop, after digging and gathering that remains in the ground, serves effectually to keep with the help of the pindars, a handsome twist in the tails of my growing stock hogs during the winter, putting them in during part of the day, and penning at night, on account of obtaining from them a portion of Arator's "gold dust."

Having now gone through the making and saving, as also the manner in which I dispose of my corn crop, with its accompaniments, you will, with your readers, be fully enabled to judge whether my system is a productive system of husbandry, or whether I have succeeded in making the "two stalks stand where one stood before"—or whether it is, or is not better to cultivate a small field well, or a large body of land in the "old way"—wear, tear, seed, labor, production, &c., considered. Or whether or not, a manuring system is the key to all very successful agricultural pursuit—or whether a man will sleep sounder after the recollection that his capital, his land, is deteriorating, or increasing in fertility. These and several other items can be readily, I think, settled, from the foregoing, as they have been by

AGRICOLA.

Alabama, April 10, 1835.

CHICKASAW PEA—PEA FODDER.

To the Editor of the Farmers' Register.

Columbia, S. C., May 11, 1835.

I send you here enclosed a few of the peas mentioned in your last number, [page 752, Vol. II.] as a dark bottle green pea, the smallest of the tribe. I prefer it to all others for fodder. Not being a running vine, but rather a bush, it is much more manageable than the common cow pea. My horses prefer it to all other fodder, and when they have it, never leave a bit, eating it all to the oldest and dryest stalk. The best practice in curing pea vines here, is not to let them remain as long in the sun as your correspondent J. M. G. intimates is necessary; but they are cut one day and housed the next, taking care not to let them be packed too close, but kept open by poles or rails being put here and there between them, and kept so for three or four weeks, when the poles or rails are withdrawn, and the fodder may be then packed as close as convenient. Or a pen is made with rails, is filled up with a few sticks between, and the whole covered with a few boards. The pea herein sent, is called Chickasaw pea; by whom and why it was so called, I do not know; but I sent many years ago one or two gallons of them to the Editor of the American Farmer in Baltimore, and having forgotten this circumstance, he sent me a few in a letter by the name of Chickasaw pea. I do not think it a native of this country, but have reason to believe it came from the East Indies. This is the plant that would make a most excellent and convenient green dressing for land, were it not as good as it is for fodder. The best way of planting it is in beds two or three feet apart, and ten to fifteen inches in the beds. I usually set one or two gatherings of the pods for seed, and cut them one day, and the next tie them in small bundles and house them as above.

My Florida coffee is coming up very well, and I am pretty well satisfied by its appearance, that it is a "*cassia*"—but what species remains to be seen.

N. HERBEMONT.

From the Silk Culturist.

PROFITS OF SILK CULTURE IN CONNECTICUT.

The following facts have been communicated to the Executive Committee [of the Silk Society] by Mr. Harvey Clark, a respectable inhabitant of Mansfield, in this State.

Mr. Clark is the proprietor of two acres of land in Mansfield, of which about half an acre is covered with mulberry trees. He has made annually from these trees about 35 lbs. of raw silk, which for the last year or two has been reeled in the improved method. The leaves have usually been gathered and the worms fed for the first three weeks by Mrs. Clark and a young woman who lives in the family. After the first three weeks, Mr. Clark also devotes himself entirely to the business. The silk has been reeled exclusively by Mrs. Clark and the young woman above alluded to, at the rate of about one pound and a half a day. During the whole silk season they have also had the care of a family of eight small children. Mr. Clark has sold his raw silk this year at four dollars per lb. and has also received a premium of 50 cents per lb. from the State Treasury. We have reason to believe that the same silk might have been sold at Lyons, or to silk merchants at New York, for five dollars per lb. Mr. Clark's mulberry trees are forty or fifty years old, and of a large size. They have been manured and cultivated with great care for the last fifteen years. Mr. Clark thinks that an acre of land covered with trees equal to those on his land will yield about 70 lbs. of silk a year. His silk house, or cocoonery, is fifty feet long and sixteen feet wide, and one story or about eight or ten feet high, not lathed or plastered, and may have cost $150 or $200. He has never had occasion to warm his cocoonery, as is practiced in Italy and France; indeed, this has never been done by any of the silk growers at Mansfield. Mr. Clark informs us, that at the silk factory in Mansfield reels are now propelled by water power. A very small amount of power answers the purpose. Improved reels are now made by several mechanics who live either at Mansfield or in the vicinity. Mr. Clark states, that his mulberry trees have been greatly improved by careful cultivation. We have shown Mr. Clark a statement in the last number of the Cultivator, of the profits made by Mr. Carrier of France, from an acre of mulberry trees.* He thinks that the statement is probably not exaggerated, and that an acre of well cultivated mulberry trees at Mansfield would yield a larger amount of silk.

---

* This article was translated for, and first published in the Farmers' Register, Vol. II.

From the Silk Culturist.

SUPERIOR QUALITY OF AMERICAN SILK.

From repeated experiments, Monsieur D'Homergue, is decidedly of opinion that American silk is vastly superior to European. The weight of the cocoons are nearly fifty per cent. heavier, and possess a uniformity which is not to be found in Europe. He found that eight cocoons, with their chrysalis, not selected, produced two ounces of raw silk, whereas one pound of ordinary European cocoons would be required for the same quantity. He also selected seventy-five cocoons, without chrysalis, weighing together 450 grains, which yielded 419 grains of raw silk, superior to that of France or Italy. Twelve bad cocoons also produced fifty grains of beautiful silk.

"These results," he says, "are truly surprising, as they show a superiority in the silk produced by the American worm, (at least in Pennsylvania,) over that of any other country that he has seen, which he was far from expecting when he began his experiments, and which, he believes, no one had yet suspected or imagined." He also adds "they promise an immense source of riches to the United States."

We might recite the authority of other culturists and manufacturers, but they all concur in the opinion that American silk is altogether superior to that produced in any other country.

Extract from the Massachusetts Agricultural Repository, &c. 1818.

LIST OF THE FOREST TREES OF AMERICA, DESCRIBED IN THE WORK OF M. ANDRE F. MICHAUX.

[The botanical name of each tree will be given in the larger Roman letters, followed by the most common American name in Italic, in the same line. The vulgar names used in various parts of the United States, or Canada, next follow in smaller letters.]

Pinus rubra—*Red pine.*

Red pine, only name given to this tree in Canada; often used in Nova Scotia and New Brunswick, and in Maine. *Norway pine*, name more generally in use for this tree than the above, in the district of Maine, New Hampshire, and Vermont, but less proper. It is not the Norway pine, says Michaux. *Yellow pine*, name sometimes given to it in Nova Scotia. *Pin rouge*, or red pine in Canada. Michaux prefers red pine, as being more characteristic and distinct.

Pinus rupestris—*Gray pine.*

Gray pine, in Canada, by the French and English. *Scrub pine*, in Nova Scotia and Maine. Uncommon and ordinary. Michaux.

Pinus mitis—*Yellow pine.*

Yellow pine, general name in all the middle states. *Short-leaved pine*, in the southern states. *Spruce pine*, a secondary name in these last mentioned states.

This is described by Michaux as a pretty valuable tree, ranking after the red pine, which is again put far behind the long-leaved or pitch pine of the south, and the white pine of the north.

Pinus inops—*Jersey pine.*

Jersey pine, general name in New Jersey, where it abounds. *Scrub pine*, the name given to it in Virginia, and in those parts of Pennsylvania where it is found,

Pinus pungens—*Table-mountain pine.*

Table-mountain pine, the only name given to it in the neighborhood of that mountain, in North Carolina.

Pinus australis—*Long-leaved pine.*

Yellow pine. Long-leaved pine. Pitch pine, (not the pitch pine of the north.) *Broom pine*, all which names are more or less used in the lower parts of the southern states, where alone this tree grows. *Southern pine* and *red pine*, are the names given to it in the middle and northern states, by those who use it. *Georgia pitch pine*, name given to it in the West Indies, and in England.

Pinus serotina—*Pond pine.*

Pond pine, name given by M. Michaux to this pine, which has none given to it in the southern states, where he found it.

Pinus rigida—*Pitch pine.*

Pitch pine, general name in all the northern and middle states. This is the true pitch pine of New England, but very different from the pitch pine of the south.

Pinus tœda—*Loblolly pine.*

Loblolly pine, only name in the southern states. *White pine*, sometimes so called in the neighborhood of Petersburg, Virginia.

Pinus strobus—*White pine.*

White pine, only name given to this tree in the greater part of the United States, and in Nova Scotia and New Brunswick. *Pumpkin pine* and *sapling pine*, names sometimes given to it in Vermont, New Hampshire, and Maine, in reference to the quality of its wood. *Pin blanc*, or *white pine*, by the Canadians. *Weymouth pine*, in England.

Abies nigra—*Black spruce, (double spruce.)*

Black, or *double spruce*, name used in the northern states, in Maine, and Nova Scotia. *Red spruce*, in the same countries, having regard, however, to trees of larger size than usual, or to certain places of growth. *Epinette noire*, in Canada. *Sapinette noire*, in France.

Abies alba—*White spruce.*

White, or *single spruce*, names applied in the northern states, and in Nova Scotia. *Epinette blanche*, in Canada. *Sapinette blanche*, in France.

Abies Canadensis—*Hemlock spruce.*

Hemlock, or *hemlock spruce*, only denomination in use in all parts of the United States, where this tree is found. *Pèrusse*, by the Canadians.

Abies balsamifera—*Silver fir.*

Silver fir. Fir balsam. Balm of Gilead, all names equally applied to this tree in the northern parts of the United States.

Juglans nigra—*Black walnut.*

Black walnut, only name in the southern and western states. *Noyer noir*, by the French of Canada and Louisiana.

Juglans cathartica—*Butter nut.*

Butter nut, only name in New York, and Virginia, and often applied in the northern states. *White walnut*, name much in use in Pennsylvania and Maryland. *Oil nut*, name applied in New Hampshire, Massachusetts, Vermont, and Connecticut.

Juglans olivæ-formis—*Pacane nut.*

Pacane nut, or *pacanier*, name given to this tree by the French of Louisiana, and adopted by the Americans.

Juglans amara—*Bitter nut hickory.*

Bitter nut hickory, only name applied to it in New York and New Jersey. *White hickory*, general name in Pennsylvania. *Noyer amer*, Canadian name.

Juglans aquatica—*Water bitter nut hickory*

Water bitter nut, name given to it by Michaux. It has no name in the southern states, where it grows.

Juglans tomentosa—*Mockernut hickory.*

Mockernut hickory, general name in New York and New Jersey. *Whiteheart hickory*, name sometimes applied in those states. *Common hickory*, applied in Pennsylvania, Maryland, and other southern states. *Noyer dur*, by the French of the Illinois country.

Juglans squamosa—*Shellbark hickory.*

Shellbark hickory, name in most common use in the United States. *Shagbark hickory*, name sometimes applied to the north of Connecticut river. *Kisky Thomas*, by the Dutch of New Jersey. *Noyer tendre*, by the French of Illinois.

We think M. Michaux mistaken on this point. It is the common walnut of our tables, and is almost universally called *shagbark*. In all the northern states, we know this tree by the name of walnut, and not hickory, which is a southern name.

Juglans Laciniosa—*Thick-shell-bark hickory.*

Thick-shell-bark hickory, name given to this tree in the western states, where it is confounded with the true shell, or shagbark. *Gloucesternut hickory*, known under this name only in that part of Virginia. *Springfield hickory*, another name given to this tree in the vicinity of Philadelphia.

Juglans porcina—*Pignut hickory.*

Pignut hickory, most common name in all parts of the United States. *Hognut hickory*, more usual name in some districts of Pennsylvania.

Juglans myristicæformis—*Nutmeg hickory-nut.*

Nutmeg hickory-nut, name given to it by M. Michaux, it having no name in the southern states.

Quercus alba—*White oak.*

White oak, general and unique name throughout the United States. *Chêneblanc*, by the Canadians.

Quercus muscosa—*Mossy cup oak.*

Mossy cup oak, name given by M. Michaux to a species found in the Genessee country, and near Albany.

Quercus macrocarpa—*Overcup white oak.*

Overcup white oak, general name given to it in Kentucky and Tennessee.

Quercus obtusiloba—*Post oak.*

Post oak, general name in both Carolinas, Georgia, and Tennessee. *Iron oak*, secondary name in those countries. *Box oak* and *box white oak*, name given to it in Maryland, and the parts of Virginia bordering on it.

Quercus lyrata—*Overcup oak.*

Overcup oak and *swamp-post oak*, names equally used in the lower parts of the southern states. *Water-white oak*, secondary name in the same places.

Quercus prinus discolor—*Swamp white oak.*

Swamp white oak, most common name in the northern and middle states. *Water-chestnut oak*, Pennsylvania name.

Quercus prinus palustris—*Chestnut white oak.*

Chestnut white oak, name applied in the lower parts of Georgia, and the Carolinas. *White oak*, peculiarly so called on the Savannah river. *Swamp-chestnut oak*, secondary name in the same places.

Quercus prinus monticola—*Rock-chestnut oak.*

Rock-chestnut oak, only name given to this tree in New York and Vermont. *Rock* and *rocky oak*, second name in the same countries. *Chestnut oak*, in Pennsylvania and Virginia.

Quercus prinus acuminata—*Yellow oak.*

Yellow oak, name given to this tree in the county of Lancaster, Pennsylvania. No particular name given to it in other parts of the United States.

Quercus prinus chinquapin—*Chinquapin oak.*

Chinquapin oak, name employed in the upper parts of Georgia, and the Carolinas. *Small-chestnut oak*, in New York and Pennsylvania.

Quercus Virens—*Live oak.*

Live oak, only name in all the southern states; and also in the northern states, where the wood is only seen, but the tree is never found.

Quercus Phellos—*Willow oak.*

Willow oak, only name in the southern states, and in Pennsylvania.

Quercus imbricaria—*Laurel oak.*

Laurel oak, secondary name in the states west of the Alleghany mountains. *Black-jack oak*, more common, but less proper name, because it is applied to another, for which it is kept distinct. *Chêne à latte*, by the Illinois French.

Quercus cinerea—*Upland willow oak.*

Barren's willow oak, name given in the lower parts of the southern states.

Quercus pumila—*Running oak.*

Running oak, in the lower parts of the southern states.

Quercus heterophylla—*Bartram's oak.*

Bartram's oak, name given to an oak on Schuylkill, near Philadelphia.

Quercus aquatica—*Water oak.*

Water oak, general name in Virginia, and in the southern states.

Quercus ferruginea—*Black-jack oak.*

Black-jack oak, name in use in the southern states. *Barren's oak*, name employed in Pennsylvania, New Jersey, and Delaware.

Quercus banisteri—*Bear oak.*

Bear oak, name in New Jersey and New York. *Black scrub oak*, name used in the north of Connecticut river. *Scrub oak*, in some parts of Pennsylvania and Virginia.

Quercus catisbæi—*Barren's scrub oak.*

Barren's scrub oak, in the lower parts of the two Carolinas and Georgia.

Quercus falcata—*Spanish oak.*

Spanish oak, only name in use in Pennsylvania, Maryland, and Virginia. *Red oak*, in the lower parts of the southern states.

Quercus tinctoria—*Black oak.*

Black oak, only name in the forests of the middle, western, and southern states. *Quercitron oak*, name in commerce. *Chêne noir*, by the Illinois French.

Quercus coccinea—*Scarlet oak.*

Scarlet oak, name given by M. Michaux to a tree, which, in the middle states, bears the name of *red oak*, being confounded with a species hereafter mentioned.

Quercus ambigua—*Gray oak.*

Gray oak, only name given to this species in New Hampshire and Vermont, as well as in the district of Maine, New Brunswick, and Nova Scotia.

Quercus palustris—*Pine oak.*

Pine oak, name given to this species in New York and New Jersey. *Swamp Spanish oak*, in Pennsylvania and Maryland.

Quercus rubra—*Red oak.*

Red oak, name given to this oak in all the northern and middle states.

In all 27 species of oaks.

Betula papyracea—*Canoe birch.*

Canoe and *paper birch*, names equally used in New Hampshire, Vermont, district of Maine, Nova Scotia, and further north. *White birch*, name also equally applied in the same countries. *Bouleau à canot*, by the French in Canada.

Betula populifolia—*White birch.*

White birch, general name in the northern and middle states. *Old-field birch.*

Betula rubra—*Red birch.*

Red birch, so called in New Jersey and some parts of Pennsylvania. *Broom birch*, secondary name in Pennsylvania. *Birch*, in the southern states.

Betula lenta—*Black birch.*

Black birch, denomination applied to it in the northern and middle states, *Cherry birch*, secondary name in some parts of the northern states *Sweet birch*, in the middle states. *Mountain mahogany*, in a part of Virginia. *Cherry birch*. *Bouleau cerisier*, by the Canadians.

Betula lutea—*Yellow birch.*

Yellow birch, name given to this species in Vermont and New Hampshire, as well as in Maine and New Brunswick.

Castanea vesca—*Chestnut.*

Chestnut, only name given to it in all parts of the United States where it grows.

Castanea pumila—*Chincapin.*

Chincapin, only denomination given to it in the middle, southern, and western states.

Fagus Sylvestris—*White beech.*

Beech, in the middle and southern states. *White beech*, in the northern states and district of Maine.

Fagus Ferruginea—*Red beech.*

Red beech, in the northern states, and district of Maine.

Chamærops palmeto—*Cabbage tree.*

Cabbage tree, or *palmetto*, in the southern states. This tree is extensively used in the construction of wharves in Charleston, South Carolina, being free from the ravages of the worms.

Ilex opaca—*American holly.*

American holly, so called in all the parts of the United States where it grows.

Diospiros Virginiana—*Persimmon tree.*

Persimmon, only name in these parts of the United States where it is found, being in the middle and southern states. *Plaqueminier*, by the Louisianians.

Acer Eriocarpum—*White maple.*

White maple, only name on the borders of the Ohio, and the rivers which fall into it. *Soft maple*, in the Atlantic states, where it is often confounded with the *scarlet maple*. *Sir wager maple*, name applied to it in England, where it has been introduced.

Acer Rubrum—*Red-flowering maple.*

Red-flowering maple. Swamp maple. Soft maple, denominations in the Atlantic states. *Scarlet-flowering maple*, principally in Virginia; and *soft maple* in New York and New Jersey. *Maple tree*, in Pennsylvania, Virginia, and Ohio, to the west of the Aleghany Mountains *Erable plaine*, by the Canadians.

Acer saccharinum—*Sugar maple.*

Sugar maple, general name; which however prevails only in the middle states, to the east of the mountains. *Rock maple*, name which prevails to the north of the Hudson river. *Hard maple*, another name in the northern states. *Erable sucré*, Canadian name.

Acer nigrum—*Black sugar maple.*

Sugar tree, general name in the country on the Ohio, and the rivers which fall into it; and often applied also there, to the last mentioned species. *Black sugar tree*, name sometimes applied, and to be preferred.

Acer negundo—*Box elder.*

Box elder, only name in the western states, where the tree is most known. *Ash-leaved maple*, name given sometimes in the Atlantic states. *Erable à giguière*, by the Illinois French.

Acer Striatum—*Moose wood.*

Moose wood, common name in all the northern states, in New Brunswick and Nova Scotia. *Striped maple*, by some persons in the middle states.

Nyssa grandidentata—*Large tupelo.*

Large tupelo, most general name in the southern states. *Water tupelo*, secondary name in the same states.

Nyssa capitata—*Sour tupelo.*

Sour tupelo, in Georgia.

Nyssa Sylvatica—*Black gum.*

Black gum tree, in all the states to the south of the Delaware. *Sour gum*, secondary name in the same states. *Peperidge*, by the Dutch of New Jersey.

Gymnocladus dioica—*Coffee tree.*

Coffee tree, only name given in the western states. *Chicot*, by the Canadians. By some botanists called *guilandina dioica.*

Pinckneya pubens—*Georgia bark.*

Georgia bark tree, name given by M Michaux; it is known by no name in that country.

Cupressus disticha—*Cypress.*

Cypress, general name in the United States. It is not known at all in the northern states, except in modern plantations, and there called *deciduous cypress*. *Bald cypress*, name less used. *Black*, or *white cypress*, having regard to the color of the wood.

Cupressus thuyoides—*White cedar.*

White cedar, only name in the states of New York, New Jersey, Delaware, and Pennsylvania. *Juniper*, in Maryland, Virginia, and North Carolina.

Thuya occidentalis—*Arbor vitæ.*

Arbor vitæ, secondary name in the district of Maine. *White cedar*, name more used in Maine, Vermont, and New Hampshire. *Cedreblanc*, by the Canadians.

Larix Americana—*American larch.*

American larch, general name given to this tree in all parts of the United States where it grows. *Hackmatack*, more used in the north, and in the district of Maine. *Tamarach*, by the Dutch of New Jersey.

N. B. This tree is very seldom called by the name of larch in New England, and, in some districts, it is called *juniper.*

Juniperus Virginiana—*Red cedar.*

Red cedar, only name given to this tree in all parts of the United States where it grows.

Q. Is it not sometimes called *savin?*

Olea Americana—*Devil wood.*

Devil wood, name given to this tree on the Savannah river, in Georgia.

N. B. We doubt the expediency of establishing this unfashionable name to any tree.

Carpinus ostrya—*Iron wood.*

Iron wood, only name in all the states to the south of the Hudson. *Lever wood*, in the district of Maine and Vermont.

Carpinus Americana—*American hornbeam.*

American hornbeam, only name given to this tree throughout the United States.

We doubt whether it is ever called any thing but simply, *hornbeam.*

Hopea tinctoria—*Sweet leaves.*

Sweet leaves, only name in use in the southern states.

Malus coronaria—*Crab apple.*

Crab apple, name given to this tree in all the southern states.

Q. Is this a native or indigenous tree?

Mespilus arborea—*June berry.*

June berry, name given to this tree in the middle states. *Wild pear*, in the district of Maine.

Magnolia grandiflora—*Large magnolia.*

Large magnolia, most common name in the cities of the southern states. *Big laurel*, in the country of the southern states. *Laurier tulipier*, by the Louisianians.

Magnolia glauca—*Small magnolia.*

Small magnolia, name given to this tree by many persons in New York and Philadelphia, as well as in some parts of New Jersey. *Swamp sassafras*, secondary name at a given distance from the above cities. *Sweet bay, white bay*, and *swamp laurel*, names more used in the southern states. *Beaver wood*, name formerly given to it in New Jersey.

Magnolia acuminata—*Magnolia cucumber tree.*

Cucumber tree, only denomination in all the western states, and along the Alleghany Mountains.

Magnolia cordata—*Heart-leaved magnolia.*

The heart-leaved magnolia, name given to this species in Upper Georgia, and which is confounded with the preceding.

Magnolia tripetala—*The umbrella tree.*

The umbrella tree, only name given to this tree in the middle and southern states.

Magnolia auriculata—*The ear-leaved magnolia.*

The ear-leaved magnolia. Indian physick, denomination most in use in the mountains of North Carolina and Virginia, but less proper. *Long-leaved cucumber tree*, second name in the same countries.

Magnolia macrophylla—*Large-leaved magnolia.*

Large-leaved magnolia, name given by M. Michaux to this species, which is confounded with the next preceding one.

Fraxinus Americana—*White ash.*

White ash, only name given to this species, in all parts of the United States where it grows.

Fraxinus tomentosa—*Red ash.*

Red ash, most general name in all the middle states, where this tree is most abundant.

Fraxinus Viridis—*Green ash.*

Green ash, name given by Michaux to this tree, which has none where it is found.

Fraxinus quadrangulata—*Blue ash.*

Blue ash, only name in Kentucky and Tennessee.

Fraxinus sambucifolia—*Black ash.*

Black ash, most general name in the northern and middle states. *Water ash*, secondary name in this art of the United States.

Fraxinus platicarpa—*Carolinian ash.*

Carolinian ash, name given by M. Michaux. It has none in the southern states, where he found it.

Gordonia lasyanthus—*Loblolly bay.*

Loblolly bay, only name in the southern states.

Gordonia pubescens—*Franklinia.*

Franklinia, name given by W. Bartram, in honor of Dr. Franklin.

Cornus Florida—*Dogwood.*

Dogwood, only name given to this tree in the United States. *Bois de flèche bâtard*, by the French of Louisiana.

Rhododendron maximum—*Swamp laurel.*

Swamp laurel, so called on the Alleghany Mountains, where this tree is most abundant.

Kalmia latifolia—*Mountain laurel.*

Mountain laurel, most common name in the Alleghany Mountains. *Sheep laurel*, secondary name in the same places. *Calico tree*, in some parts of the southern states.

N. B. M. Michaux considers, that this plant is not found to the north of the Hudson River. It is abundant in some parts of Massachusetts, where it is generally only a shrub. He says, it grows in Carolina to the height of 15 or 20 feet, and, as its wood is very hard, it is applied to some useful purposes in the arts.

Cerasus Virginiana—*Wild cherry.*

Wild cherry, only name given to this tree throughout the United States.

Cerasus Caroliniana—*Wild orange.*

Wild orange, only name given to this tree in the southern states.

Cerasus borealis—*Red cherry.*

Red cherry, name less used than that of small (or dwarf) cherry, but which is more appropriate.

Annona triloba—*Papau tree.*

Papau, only name given to it in the middle and western states.

Gleditsia triacanthos—*Honey locust.*

Honey locust, known under this name only, in all parts of the United States where it grows.

N. B. M. Michaux is mistaken in this general assertion. It is also called *three-thorned acacia*, in the catalogues of the nurserymen.

Gleditsia monosperma—*Swamp locust.*

Swamp locust, in the maritime parts of the southern states. *Water locust*, secondary name in the same parts of the southern states.

Laurus sassafras—*Sassafras.*

Sassafras, only name given to this tree in the United States.

Laurus caroliniensis—*Red bay.*

Red bay, only name given to this tree in the maritime parts of the southern states.

Platanus occidentalis—*Button wood.*

Button wood, name generally given in the United States, particularly the Atlantic ones. *Plane* and *sycamore*, names more used in the western states. *Water beech*, name given to it in some parts of Maryland and Virginia. *Colonier*, by the French of Upper Louisiana.

Liquidambar styraciflua—*Sweet gum.*

Sweet gum, only name in the United States.

Lyriodendron tulipifera—*Poplar*, or *tulip tree.*

Poplar, general name in the United States. N. B. This is an evident mistake of M. Michaux. It is seldom called poplar, and it is an improper name to be affixed to it, as its popular one. *Tulip tree*, most common name in the northern states, where it is only known as a cultivated tree. *Yellow* or *white poplar. White wood*, name in the Genesee country.

Bignonia catalpa—*Catalpa tree.*

Catalpa tree, general name in the southern states.

Andromeda arborea—*Sorel tree.*

Sorel tree, name given to this tree on the Alleghany Mountains, and in the middle states.

Celtis occidentalis—*Nettle tree.*

Nettle tree, in all the United States. N. B. We doubt its having such, or any other name in the northern states.

Celtis crassifolia—*Hackberry tree.*

Hackberry tree, only name given to it in Kentucky and Tennessee. *Hoop ash*, upon the borders of the Ohio river, in Pennsylvania and Virginia. *Black elder*, less common name in the same places.

Morus rubra—*Red mulberry.*

Red mulberry, only name given to this tree in all the United States.

Pavia lutea—*Buck eye.*

Buck eye, only name given to it on the Alleghany Mountains, and in the western states.

M. Michaux ought to have added, that it is also called the *yellow-horse chestnut.*

Æculus Ohioensis—*Ohio buck eye.*

Ohio buck eye, name given by M. Michaux, who claims to have been the first who distinguished it.

N. B. The popular name of this tree ought also to be either American, or Ohio horse chestnut; for M. Michaux admits it is in truth a horse chestnut, and it would be very embarrassing to admit such confusion in popular names.

Robinia pseudo-acacia—*Locust tree.*

Locust tree, general name in the United States. *Yellow locust, red locust, black locust*, different names given to this tree on the Susquehannah, having regard to the varied color of the wood.

Robinia viscosa—*Rose-flowering locust.*

Rose-flowering locust, name given by M. Michaux to this tree in the Cherokee country, where it has no peculiar name. N. B. It has, however, been called so elsewhere.

Virgilia lutea—*Yellow wood.*

Yellow wood, name given to this tree in Tennessee.

Ulmus Americana—*White elm.*

White elm, general name given to this tree, in all parts of the United States where it grows. Michaux.

N. B. We doubt the generality of this application. It is new to us. It is generally called, in the vicinity of Boston, *American elm*, or simply *elm*.

Ulmus alata—*Wahoo.*

Wahoo, name given to this species in the maritime parts of the southern states.

Ulmus rubra—*Red elm.*

Red elm, most common name in all parts of the United States where it grows. *Slippery elm*, secondary name in New York and New Jersey. *Moose elm*, in the upper parts of New York. *Orme gras*, by the Illinois French.

Planera ulmifolia—*Planer tree.*

Planer tree, name given to it to preserve the memory of some individual. Michaux.

N. B. We are not told who this personage was, nor why the tree (as M. Michaux, in the French idiom remarks) was *consecrated* to him.

Populus tremuloides—*American aspen.*

American aspen, name given to this tree in the northern and middle states. Michaux. N. B. Sometimes called aspen poplar, and sometimes poplar only.

Populus grandidentata—*American large aspen.*

American large aspen, name given by M. Michaux to this species, which is ordinarily confounded with the preceding one.

Populus argentea—*Cotton tree.*

Cotton tree, known by this name on the Savannah river.

Populus hudsonica—*American black poplar.*

American black poplar, name given by M. Michaux to a species (as he says) before destitute of a name.

Populusmonilifera—*Virginian poplar.*

Virginian poplar, name given in Europe to this species.

Populus canadensis—*Cotton wood.*

Cotton wood, name given to this tree on the Mississippi, and the rivers which flow into it.

Populus angulata—*Carolinian poplar.*

Carolinian poplar, name given to it in Europe, because first brought from Carolina.

Populus Balsamifera—*Balsam poplar.*

Balsam poplar, known under this name in Canada.

N. B. It is probable M. Michaux means by this or the next, the tree which is called *black poplar*, *tacamahac*, and *balm of Gilead poplar* in the state of Massachusetts.

Populus candicans—*Heart-leaved balsam poplar.*

Heart-leaved balsam poplar.

N. B. If this is a different species from the last, it is the tacamahac of Massachusetts.

Tilia Americana—*Bass wood.*

Bass wood, prevailing name in the northern and middle states. *Lime*, name almost as frequent.

Tilia alba—*White lime.*

White lime, this species on the Ohio, is confounded with the last.

Tilia pubescens—*Downy lime tree.*

Downy lime tree, thus called in the southern states.

Alnus serrulata—*Common alder.*

Common alder, in all the United States.

Alnus glauca—*Black alder.*

Black alder, in Vermont.

Salix nigra—*Black willow.*

Black willow, general name in all the United States.

Salix ligustrina—*Champlain willow.*

Champlain willow, name given by M. Michaux, who found it on Lake Champlain in great plenty.

Salix lucida—*Shining willow.*

Shining willow, name given by M. Michaux.

From the Library of Useful Knowledge—Farmer's Series.

THE VICES, AND DISAGREEABLE OR DANGEROUS HABITS OF THE HORSE.

The horse has many excellent qualities, but he has likewise defects, and these occasionally amounting to vices. Some of them may be attributed to natural temper; for the human being scarcely discovers more peculiarities of habit and disposition, than does the horse. The majority of them, however, as perhaps in the human being, are consequences of a faulty education. Their early instructor has been both ignorant and brutal, and they have become obstinate and vicious.

Restifness.

At the head of the vices of the horse we place *restifness*, the most annoying, and the most dangerous of all. It is the produce of bad temper and worse education; and, like all other habits founded on nature and stamped by education, it is inveterate. Whether it appears in the form of kicking, or rearing, or plunging, or bolting, or in any way that threatens danger to the rider or the horse, it rarely admits of cure. A determined rider may, to a certain degree, subjugate the animal; or the horse may have his favorites, or form his attachments, and with some particular person he may be comparatively or perfectly manageable; but others cannot long depend upon him, and even his master is not always sure of him. We will speak of the most likely means of cure, or escaping from danger, as it regards the principal forms under which restifness displays itself; but we must premise as a rule that admits of very few exceptions that, he neither displays his wisdom, nor consults his safety, who attempts to conquer a restiff horse.

An excellent veterinary surgeon, and a man of great experience in horses, Mr. Castley, truly says, in 'The Veterinarian,' 'from whatever cause the vicious habits of horses may originate, whether from some mismanagement, or from natural badness of temper, or from what is called in Yorkshire a *mistetch*, whenever these animals acquire one of them, and it becomes in some degree confirmed, they very seldom, if ever, altogether forget it. In reference to driving, it is so true, that it may be taken as a kind of aphorism, that if a horse kicks once in harness, no matter from what cause, he will be liable to kick ever afterwards. A good coachman may drive him, it is true—and may make him go, but he cannot make him forget his vice; and so it is in riding. You may conquer a restiff horse; you make him ride quiet for months, nay, almost for years together, but I affirm, that under other circumstances, and at some future opportunity, he will be sure to return to his old tricks again.'

Mr. Castley gives two singular and conclusive instances of the truth of this doctrine. 'When a very young man,' says he, 'I remember purchasing a horse at a fair in the north of England, that was offered very cheap on account of his being unmanageable. It was said that nobody could ride him. We found that the animal objected to have any thing placed upon his back, and that, when made to move forward with nothing more than a saddle on, he instantly threw himself down on his side with great violence, and would then endeavor to roll upon his back.

'There was at that time in Yorkshire, a famous colt-breaker, known by the name of Jumper,* who was almost as celebrated in that country for taming vicious horses into submission, as the famed Whisperer was in Ireland. We put this animal into Jumper's hands, who took him away, and in about ten days brought him home again, certainly not looking worse in condition, but perfectly subdued and almost as obedient as a dog: for he would lie down at this man's bidding, and only rise again at his command, and carry double or any thing. I took to riding him myself, and may say, that I was never better carried for six or eight months, during which time he never showed the least vice whatever. I then sold him to a Lincolnshire farmer, who said that he would give him a summer's run at grass, and show him a very fine horse at the great Horncastle fair.

'Happening to meet this gentleman the following year, I naturally enough inquired after my old friend. "Oh!" said he, "that was a bad business —the horse turned out a sad rebel. The first time we attempted to mount him, after getting him up from grass, he in an instant threw the man down with the greatest violence, pitching him several yards over his head: and after that he threw every one that attempted to get on his back. If he could not throw his rider, *he would throw himself down*. We could do nothing with him, and I was obliged at last to sell him to go in a stage-coach." '

* Those of our readers who were connected with the contested elections for Yorkshire, will recollect Jumper, covered with orange plush from top to toe, and scampering in every direction over the country. Sometimes he would exchange this for a bear-skin, enveloped in which, and mounted occasionally on a buffalo, he was a most formidable object. He had extraordinary power over animals of various species, for he tamed to the saddle a buffalo for Mr. Tempest, and a pair of rein-deer for harness for Lord Fitzwilliam. But his charm consisted chiefly in fearlessness, and brute force, accompanied by considerable tact. He would generally try rough measures first; and in his perilous encounters with some of his troublesome scholars, had nearly every bone in his body fractured. Sullivan's method was altogether different—force was rarely resorted to. The enemy surrendered to him at discretion and without a struggle. Jumper, however, seemed to have some charm about him, for when he had, by dint of punishment, striven in vain to conquer an unruly horse in the market-place of Wakefield—he alighted—stood on the near side of the horse—brought the animal's head almost back to his off shoulder by forcibly pulling at the off rein, and then sternly gazed at him over the withers for two or three minutes. The animal began to tremble, and broke out into a profuse perspiration. Jumper then loosened his hold of the rein, and patted and caressed the horse, who immediately followed him round the market-place perfectly tamed.

In the next story, Jumper's counterpart and superior, the Irish Whisperer, is brought on the stage, and, although he performs wonders, *he* cannot radically cure a restiff horse. 'At the Spring Meeting of 1804, Mr. Whalley's *King Pippin* was brought on the Curragh of Kildare to run. He was a horse of the most extraordinary savage and vicious disposition. His particular propensity was that of *flying at and worrying* any person who came within his reach, and if he had an opportunity, he would get his head round, seize his rider by the leg with his teeth, and drag him down from his back. For this reason he was always ridden in what is called *a sword;* which is nothing more than a strong flat stick, having one end attached to the cheek of the bridle, and the other to the girth of the saddle, a contrivance to prevent a horse of this kind from getting at his rider.

'King Pippin had long been difficult to manage and dangerous to go near, but on the occasion in question he could not be got out to run at all. *Nobody could put the bridle upon his head.* It being Easter Monday, and consequently a great holyday, there was a large concourse of people assembled at the Curragh, consisting principally of the neighboring peasantry; and one countryman, more fearless than the rest of the lookers-on, forgetting, or perhaps never dreaming that the better part of courage is discretion, volunteered his services to bridle the horse. No sooner had he committed himself in this operation, than King Pippin seized him somewhere about the shoulders or chest, and says Mr. Watts (Mr. Castley's informant,) "I know of nothing I can compare it to, so much as a dog shaking a rat." Fortunately for the poor fellow, his body was very thickly covered with cloths, for on such occasions an Irishman of this class is fond of displaying his wardrobe, and if *he has three coats at all in the world*, he is sure to put them all on.

'This circumstance in all probability saved the individual who had so gallantly volunteered the forlorn hope. His person was so deeply enveloped in extra-teguments, that the horse never got fairly hold of his skin, and I understand that he escaped with but little injury, beside the sadly rent and totally ruined state of his holyday toggery.

'The Whisperer was sent for, who having arrived, was shut up with the horse all night, and in the morning he exhibited this hitherto ferocious animal, following him about the course like a dog —lying down at his command—suffering his mouth to be opened, and any person's hand to be introduced into it—in short, as quiet almost as a sheep.

He came out the same meeting, and won a race, and his docility continued satisfactory for a long time; *but at the end of about three years his vice returned*, and then he is said to have *killed a man*, for which he was destroyed.'

It may not be uninteresting in this connexion, to give some account of this tamer of quadruped vice. However strange and magical his power may seem to be, there is no doubt of the truth of the account that is given of him. The Rev. Mr. Townsend, in his Statistical Survey of Cork, first introduced him to the notice of the public generally, although his fame had long spread over that part of Ireland. We, however, give the following extract from Croker's Fairy Legends and

Traditions of Ireland, Part II. p. 200, for the fact seems the work of some elfin sprite, rather than of a rude and ignorant horse-breaker.

'He was an awkward, ignorant rustic of the lowest class, of the name of Sullivan, but better known by the appellation of the Whisperer; his occupation was horse-breaking. The nickname he acquired from the vulgar notion of his being able to communicate to the animal what he wished by means of a whisper, and the singularity of his method seemed in some degree to justify the attribute. In his own neighborhood, the notoriety of the fact made it seem less remarkable, but I doubt if any instance of similar subjugating talent is to be found on record. As far as the sphere of his control extended, the boast of *veni, vidi, vici*, was more justly claimed by Sullivan than by Cæsar himself.

'How his art was acquired, and in what it consisted, is likely to be for ever unknown, as he has lately (about 1810) left the world without divulging it. His son, who follows the same trade, possesses but a small portion of the art, having either never learned the true secret, or being incapable of putting it into practice. The wonder of his skill consisted in the celerity of the operation, which was performed in privacy without any apparent means of coercion. Every description of horse, or even mule, whether previously broken or unhandled, whatever their peculiar habits or vices might have been, submitted without show of resistance to the magical influence of his art, and in the short space of half an hour became gentle and tractable. This effect, though instantaneously produced, was generally durable. Though more submissive to him than to others, they seemed to have acquired a docility unknown before.

'When sent for to tame a vicious beast, for which he was either paid according to the distance, or generally two or three guineas, he directed the stable, in which he and the object of the experiment were, to be shut, with orders not to open the door until a signal was given. After a *tête-à-tête* of about half an hour, during which little or no bustle was heard, the signal was made, and, upon opening the door, the horse appeared lying down, and the man by his side, playing with him like a child with a puppy dog. From that time he was found perfectly willing to submit to any discipline —however repugnant to his nature before.' 'I once,' continues Mr. Townsend, 'saw his skill tried on a horse, which could never before be brought to stand for a smith to shoe him. The day after Sullivan's half hour's lecture, I went, not without some incredulity, to the smith's shop, with many other curious spectators, where we were eye-witnesses of the complete success of his art. This, too, had been a troop horse, and it was supposed, not without reason, that after regimental discipline had failed, no other would be found availing. I observed that the animal appeared terrified whenever Sullivan either spoke or looked at him; how that extraordinary ascendancy could have been obtained, is difficult to conjecture.

In common cases this mysterious preparation was unnecessary. He seemed to possess an instinctive power of inspiring awe, the result, perhaps, of natural intrepidity, in which, I believe, a great part of his art consisted; though the circumstance of the *tête-à-tête* shows that, on particular occasions, something more must have been added to it. A faculty like this would in some hands have made a fortune, and I understand that great offers were made to him, for the exercise of his art abroad. But hunting was his passion. He lived at home in the style most agreeable to his disposition, and nothing could induce him to quit Duhallow and the fox hounds.'

Mr. Castley witnessed the total failure of the younger Sullivan. He says, 'we have in the regiment a remarkably nice horse, called Lancer, that has always been very difficult to shoe, but seven or eight years ago, when we first got him, he was downright vicious in that respect. When the regiment was stationed at Cork, the farrier-major sought out the present Sullivan, the son of the celebrated Whisperer, and brought him up to the barracks in order to try his hand upon Lancer, and make him more peaceable to shoe; but I must say this person did not appear to possess any particular controlling power over the animal, more than any other man. Lancer seemed to pay no attention whatever to his charm, and, at last fairly beat him out of the forge. Time, however, and a long perseverance in kind and gentle treatment, have effected what force could not. The horse is now pretty reasonable to shoe.'

Backing or gibbing.

One of the first species of restiffness, taking them in alphabetical order, is backing or gibbing. These are so closely allied that we hardly know how to separate them. Some horses have the habit of backing at first starting, and that more from playfulness than desire of mischief. A moderate application of the whip will usually be effectual. Others, even at starting, exhibit considerable obstinacy and viciousness. This is frequently the effect of bad breaking. Either the shoulder of the horse had been wrung when he was first put to the collar, or he had been foolishly accustomed to start in the break *up hill*, and, therefore, all his work coming upon him at once, when it being much more difficult to draw the break up-hill, than to back and let it run down-hill, he gradually acquired this dangerous habit.

A hasty and passionate breaker will often make a really good tempered young horse an inveterate gibber. Every young horse is at first shy of the collar. If he be too quickly forced to it, he will possibly take a dislike to it, that will occasionally show itself in the form of gibbing as long as he lives. The judicious horse-breaker will resort to no severity, even if the colt should go out several times without touching collar. The example of his companion will ultimately induce him to take to it voluntarily and effectually.

A large and heavy stone should be put behind the wheel before starting, when the horse, finding it more difficult to back than to go forward, will gradually forget this unpleasant trick. It will likewise be of advantage, as often as it can be managed, so to start that the horse shall have to back up-hill. The difficulty of accomplishing this will soon make him readily go forward at once. A little coaxing, or leading, or moderate flagellation, will assist in accomplishing the cure.

When, however, a horse, thinking that he has had enough of work, or has been improperly checked or corrected, or beginning to feel the painful pressure of the collar, swerves, and gibs, and backs, it is a more serious matter. Persuasion should here first be tried; and, afterwards, reasonable coercion, but no cruelty: for the brutality which is often exercised in attempting to compel a gibbing horse to throw himself habitually into the collar, never yet accomplished the purpose. The horse may, perhaps, be whipped into motion, but if he has once begun to gib, he will have recourse to it again whenever any circumstance displeases or annoys him; and the habit will be rapidly, and so completely formed, that he will become insensible to all severity.

It is useless and most dangerous to contend with a horse determined to back, unless there is plenty of room, and, by tight reining, the driver can make him back in the precise direction he wishes, and especially up-hill. Such a horse should be immediately sold, or turned over to some other work. In a stage-coach as a wheeler, and particularly as the near-wheeler; or, in the middle of a team at agricultural work, he may be serviceable. It will be useless for him to attempt to gib there, for he will be dragged along by his companions whether he will or no; and, finding the inutility of resistance, he will soon be induced to work as well as any horse in the team. This reformation will last while he is thus employed, but, like restiness generally, it will be delusive when the horse returns to his former occupation. The disposition to annoy will very soon follow the power to do it. Some instances of complete reformation have occurred, but they have been rare.

When a horse, not often accustomed to gib, betrays a reluctance to work, or a determination not to work, common sense and humanity will demand that some consideration should be taken, before measures of severity be resorted to. The horse may be taxed beyond his power. He soon discovers whether this is the case, and by refusing to proceed, tells his driver that it is so; and the utmost cruelty will not induce many horses to make the slightest effort, when they are conscious that their strength is inadequate to the task. Sometimes the withers are wrung, and the shoulders sadly galled; and the pain, which is intense on level ground and with fair draught, becomes insupportable when he tugs up a steep acclivity. These things should be examined into, and, if possible, rectified; for, under such circumstances, cruelty might produce obstinacy and vice, but not willing obedience.

Those who are accustomed to horses know what seemingly trivial circumstances occasionally produce this vice. A horse, whose shoulders are raw, or that have frequently been so will not start with a cold collar. When the collar has acquired the warmth of the parts on which it presses, the animal will go without reluctance. Some determined gibbers have been reformed by constantly wearing a false collar, or strip of cloth round the shoulders, so that the coldness of the usual collar should never be felt; and others have been cured of gibbing by keeping the collar on night and day, although the animal is not able to lie down so completely at full length, which the tired horse is always glad to do. When a horse gibs, not at starting but while doing his work, it has sometimes been useful to line the collars with cloth instead of leather; the perspiration is readily absorbed, the substance which presses on the shoulders is softer, and it may be far more accurately eased off at a tender place.

Biting.

This is either the consequence of natural ferocity or a habit acquired from the foolish and teasing play of grooms and stable boys. When a horse is tickled and pinched by thoughtless and mischievous youths, he will first pretend to bite his tormentors; by degrees he will proceed further, and actually bite them, and, very soon after that, he will be the first to challenge to the combat, and without provocation seize some opportunity to gripe the incautious groom; and then, as the love of mischief is a propensity too easily acquired, this war half playful, and half in earnest, will become habitual to him, and will degenerate into absolute viciousness. Nothing can here be done in the way of cure; kindness would aggravate the evil, and no degree of severity will correct it. Prevention, however, is in the power of every proprietor of horses. While he insists on gentle and humane treatment of his cattle, he should systematically forbid this horse-play. It is that which can never be considered as operating as a reward, and thereby rendering the horse tractable; nor does it increase the affection of the animal for his groom, because he is annoyed and irritated by being thus incessantly teased.

Getting the cheek of the bit into the mouth.

Some horses that are disposed to be mischievous try to do this, and are very expert at it. They soon find what advantage it gives them over their driver; who by this manœuvre loses almost all command. Harsh treatment is here completely out of the question. All that can be done is, by some mechanical contrivance, to render the thing difficult or impossible, and this may be managed by fastening a round piece of leather on the inside of the cheek of the bit.

Kicking.

This, as *a vice*, is another consequence of the culpable habit of grooms and stable-boys of teasing the horses. That which is at first an indication of annoyance at the pinching and tickling of the groom, and without any design to injure, gradually becomes the expression of anger, and the effort at mischief. There is no cure for this vice; and he cannot be justified who keeps such a kicking horse in his stable.

Some horses acquire a habit of kicking at the stall or the bail, and particularly at night, from mere irritability and fidgettiness. The neighboring horses are disturbed, and the kicker gets swelled hocks, or some more serious injury. This is also a habit very difficult to correct if suffered to become established. Mares are far more subject to it than horses.

Before the habit is inveterately established, a thorn bush or a piece of furze fastened against the partition or post will sometimes effect a cure. When the horse finds that he is pretty severely pricked he will not long continue to punish himself. In confirm cases it may be necessary to have recourse to the log, but the legs are often not a little bruised by it. A rather long and heavy piece of wood attached to a chain is buckled above the hock, so as to reach about half way down the leg. When the horse attempts to kick violently, his leg will receive a severe blow from this, and the repetition of the blow will soon teach him to be quiet.

A much more serious vice is kicking in harness. From the least annoyance about the rump or quarters, some horses will kick at the most violent rate, and destroy the bottom of the chaise, and endanger the limbs of the driver. Those that are fidgetty in the stable are most apt to do this. If the reins should perchance get under the tail, the violence of the kicker will be most outrageous; and while the animal presses down his tail so tightly that it is almost impossible to extricate the reins, he continues to plunge until he has demolished every thing behind him.

This is a vice standing foremost in point of danger, and which no treatment will often conquer. It will be altogether in vain to try coercion here. If the shafts are very strong and without flaw, or if they are plated with iron underneath, and a stout kicking strap used, which will barely allow the horse the proper use of his hind limbs in progression, but not permit him to raise them sufficiently for the purpose of kicking, he may be prevented from doing mischief; or if he is harnessed to a heavy cart, and thus confined, his efforts to lash out will be restrained: but it is a very unpleasant thing frequently to witness these attempts, although ineffectual, to demolish the vehicle; and the shafts or the kicking strap may possibly break, and extreme danger may ensue. A horse that has once begun to kick, whatever may have been the original cause of it, can never be depended on again; and he will be very unwise who ventures behind him.

Unsteadiness whilst being mounted.

When this merely amounts to eagerness to start (very unpleasant, indeed, at times, for many a rider has been thrown from his seat before he was fairly fixed in it,) it may be remedied by an active and good horseman. We have known many instances in which, while the elderly, and inactive, and fearful man, has been making more than one ineffectual attempt to vault into the saddle, the horse has been dancing about to his annoyance and danger; but the animal had no sooner been transferred to the management of a younger and more agile rider, than he became perfectly subdued. Severity will here, more decidedly than in any other case, do harm. The rider should be fearless—he should carelessly and confidently approach the horse, mount at the first effort, and then restrain him for a while, patting him, and not suffering him to proceed until he becomes perfectly quiet. These horses should not be too highly fed, and should daily have sufficient exercise.

When the difficulty of mounting arises not from eagerness to start, but unwillingness to be ridden, the sooner such horse is disposed of the better. He may be conquered by a determined rider, but a skilful and determined horseman alone will manage him; and even he will not succeed without frequent and even dangerous contests that will mar all the pleasure of the ride.

Rearing.

This sometimes results from playfulness, carried indeed to an unpleasant and dangerous extent; but it is oftener a vice, and is a desperate and frequently successful effort to unhorse the rider. The horse that has twice decidedly and dangerously reared, should never be trusted again, unless indeed it be the fault of the rider—unless he has been using a deep curb and sharp bit. Some of the best horses will contend against these, and then rearing may be immediately and permanently cured by using a snaffle bridle alone.

The horse-breaker's remedy, that of pulling the horse backward on a soft piece of ground, is worthy of him, and would be practised only by reckless and brutal men. Many horses have been injured in the spine, and others have broken their necks, by being thus suddenly brought over; while even the horse breaker, who fears no danger, is not always able to extricate himself from the falling horse. If rearing proceeds from vice, and is unprovoked by bruising and laceration of the mouth, it fully partakes of the inveteracy which attends the other divisions of restiveness.

Running away.

Some headstrong horses will occasionally endeavor to bolt with the best rider. Others, with their best wonted sagacity, endeavor thus to dislodge the timid or unskilful. Some are hard to hold, or bolt only during the excitement of the chase; others will run away, prompted by a vicious propensity alone. There is no cure here. That method which affords any probability of success, is to ride such a horse with a strong curb and sharp bit; to have him always firmly in hand; and if he will run away, and the place will admit of it, to give him (sparing neither curb, whip, nor spur) a great deal more running than he likes.

Vicious to clean.

It would scarcely be believed to what an extent this exists in some horses, that are otherwise perfectly quiet. It is only at a great hazard that they can be cleaned at all. The origin of this is probably some maltreatment. There is a great difference in the sensibility of the skin in different horses. Some seem as if they could scarcely be made to feel the whip; others cannot bear a fly to alight on them without the expression of annoyance. In young horses the skin is peculiarly delicate. If they have been curried with a broken comb, or hardly rubbed with an uneven brush, the recollection of the torture they have felt makes them impatient, and even vicious, during every succeeding operation of the kind. Many grooms, likewise, seem to delight in producing these exhibitions of uneasiness and vice; although when they are carried a little too far, and to the hazard of the limbs of the groom, the animals that have been almost tutored into these expressions of irritation, are brutally kicked and punished.

This, however, is a vice which may be conquered. If the animal be dressed with a lighter hand, and wisped rather than brushed, and the places where the skin is most sensitive be avoided as much as thorough cleanliness will allow, the horse will gradually lose the recollection of former ill-treatment, and become tractable and quiet.

Vicious to shoe.

The correction of this is more peculiarly the business of the smith; yet the master should diligently concern himself with it, for it is oftener the consequence of injudicious or bad usage than of natural vice. It may be expected that there will be some difficulty in shoeing a young horse for the first few times. It is an operation which gives him a little uneasiness. The man to whom he is most accustomed should go with him to the forge: and if another and steady horse were shod before him, he might be induced more readily to submit. We cannot deny, that after the habit of resisting this necessary operation is formed, force may sometimes be necessary to reduce our rebellious servant to obedience; but we affirm that the majority of horses *vicious to shoe* are rendered so by harsh usage, and by the pain of correction being added to the uneasiness of shoeing. It should be a rule in every forge that no smith should be permitted to strike a horse, much less to twitch or to gag him, without the master-farrier's order, and that a young horse should never be twitched or struck. There are few horses that may not be gradually rendered manageable for this purpose by mildness and firmness in the operator. They will soon understand that no harm is meant, and they will not depart from their usual habit of obedience; but if the remembrance of corporeal punishment is connected with shoeing, they will always be fidgety, if not dangerous.

This is a very serious vice, for it not only exposes the animal to occasional severe injury from his own struggles, but also from the correction of the irritated smith, whose limbs, and even whose life being in jeopardy, may be forgiven if he is sometimes a little two hard-handed. Such a horse is very liable, and without any fault of the smith, to be pricked and lamed in shoeing; and if the habit should be confirmed, and should increase, and it at length becomes necessary to cast him, or to put him in the trevis, the owner may be assured that many years will not pass ere some formidable and even fatal accident will take place. If therefore, mild treatment will not correct the vice, the horse cannot be too soon got rid of.

AMHERST TILLAGE.

To the Editor of the Farmers' Register.

Amherst, May 15th, 1835.

I am pleased with the Register, and believe it calculated to do much good, if our farmers would read it. I am sorry you have so few subscribers from this section, lying under the mountain, to contribute to fill its valuable columns. The desire to improve is confined to a few, and they pretty much scattered through the county—and unless a different spirit should pervade the cultivators of the soil, the west must still continue to be the final home for very many of them. I consider that the present rise in the price of tobacco will be of serious disadvantage to the small spirit of improvement that exists amongst us. All the manure on the farms, which should be applied to reclaiming the worn out parts of the land, so that the clover would take, is now applied to making tobacco; and many will even raise tobacco to buy corn. We should be glad (some of us at least) if the "Gleaner" would take an excursion through this section; as his observations upon the state of agriculture in Albemarle gave several valuable hints for the improvement of our farms.

As I wish to sow the orchard grass, and am unacquainted with the quantity that it would be proper to sow to the acre, and when it should be sown, I should be glad, if you can give the information, you would do so—if not, perhaps some of your subscribers can.

AN AMHERST FARMER.

TO KILL PERSIMMON BUSHES.

Fauquier, April 28th, 1835.

Governor Barbour in his address to the Agricultural Society of Albemarle, says, "but as yet I have found no satisfactory plan, by which successfully to root out the annoying growth to which I have referred. Severe grazing will in time, pretty effectually destroy all but the *persimmon;* nothing will eat that. And for one I am ready to pronounce him a benefactor, who will discover an effectual method of destroying it." Without intending to put in a claim for an obelisk, or a statue, or for any other memorial of my being than a small hillock in the orchard, or under the cedars of Black River, where my ancestors lie, I will inform him of what I deem to be an effectual method of destroying the persimmon bush: it is simple and cheap. From the 20th of June to the 20th of August, strip them of their leaves, taking care to pull the buds off. Where this is well done, the bush will die. They should be stripped in the field the year before it is fallowed for wheat, or the second year before it is put in corn. All bushes that are well stripped will die the first year—those that are not, should be stripped the second time. The small limbs may be pulled off.

WHEAT CROP IN MONTGOMERY, MD.

Montgomery County, Md., May 25th, 1835.

The crops of grain were never more unpromising in this neighborhood, and the season is now so far advanced that there is little hopes of their recovery. I have a small lot of three acres, upon which last year I put three hundred large cart loads of farm-pen manure—ploughed it deep with three horses, and cultivated it in potatoes. The crop of potatoes, in consequence of the dry season, was very inferior. Early in the month of November I dug the potatoes—removed all the vines and litter of every description—ploughed it with a large three-horse plough—which brought the manure which had been turned down in the spring, to the surface, finely rotted. I then harrowed it twice—sowed on it ten bushels of blue stem wheat, and shovelled it in with the double shovel plough, leaving it in nicer order than any piece of land that I had ever prepared, and calculated confidently on forty bushels of wheat per acre. From its present appearance, I should say, it would not make ten per acre, and I am confident I have no acre of land on my farm that would not, in a tolerable wheat year with common preparation, produce double. I mention this to show the complete failure this year, under apparently, the most favorable circumstances.

From the Horticultural Register.

ON THE CULTURE OF MILK-WEED.—(*Asclepias Syriaca.*)

Some four or five years since, in a conversation with George Manners, Esq. the British Consul for Massachusetts, on the various kinds of edible vegetables, cultivated in our gardens, he observed that, during a recent visit to Canada, he was informed that the young shoots of the milk-weed were used as a substitute for asparagus, and asked me if I had ever heard of their being cooked in the United States. I replied, that I perfectly recollected, when a boy, my mother often had them gathered from the fields and road-sides, with the dandelion, shepherds' sprouts, nettles, and other plants, which were collected as greens; but that I had never seen the plant thus used elsewhere, or heard it named as a culinary vegetable; but that I certainly would make an experiment in its cultivation, and as to its qualities, as an addition to our garden pot herbs.

Having collected the seed in the autumn, it was sown early in the spring in drills, and covered an inch deep. They came up freely in four or five weeks, and when the plants were two years old, I took up a portion of the roots, and set them out about eight inches apart, in a trench six inches deep. The ground had been manured and thoroughly dug over, previously to forming the trench. The following spring, when the shoots were four or five inches high, they were cut, tied up in bunches, boiled and served up with melted butter, like asparagus; and they were as tender, and to my taste quite as delicious a vegetable, resembling in flavor the youngest and most delicate string beans.

As the plant is very hardy, exceedingly prolific, easily cultivated, and such a valuable addition to our early vegetables, I consider a bed of it nearly as desirable as one of asparagus.

No better mode of cultivation can be adopted, than that for asparagus, as described by Mr. Chandler, in his interesting, instructive, and able article, which appeared in the third number of the Horticultural Register*—except the roots of the milk-weed should not be covered more than five or six inches deep.

* * * * *

Asclepias (*Swallow-wort,*) is a numerous genus of plants, there being forty-two species, which have been described by botanists, two of which only are found in Europe, but three in South America, while there are eighteen indigenous to the United States, and the others are divided between the West Indies and Africa. Many of the varieties are cultivated as ornamental plants in England and France, but the following kinds, natives of this country, are considered the most beautiful, besides being more hardy than those of more southern climes; still many of the latter are considered worthy of the green-house.

1. *Muschata,* so called by Bartram, for its strong and agreeable musk scent, is peculiar to the natural meadows of South Carolina, Georgia, and Florida. It is a low plant, of not more than five or six inches in height, with flowers of a pale green color, inclining to yellow.

2. *Venosa* has leaves elegantly variegated with white and crimson veins, and the stems terminate in an umbel of pale flesh-colored flowers.

3. *Pulchra*—water-silk-weed—has nearly erect stems, four or five feet high; umbels very small; flowers crimson purple. Grows on low, wet land, by the side of ponds.

4. *Variegata*—variegated. Leaves rough, umbels compact and come out from the side of the stalk; flowers of an herbaceous odor.

5. *Nivea*—white, or almond-leaved. Stalks two feet high, and of a dark green. Leaves deep green above, and pale beneath, smooth and rather stiff. Flowers green, with white nectaries.

6. *Incarnata*—flesh-colored—has several upright stalks about two feet high, at the top of which are produced close umbels of purple flowers. Blooms in August.

7. *Decumbens.* The stalks are declining, hairy, a foot and a half high; leaves narrow; umbels compact, at the extremity of the branches; flowers a bright orange color.

8. *Verticillata.* Stalks slender, upright; umbels at the extremity of the stems; leaves in whorls of four, five, and six together; flowers small and of a greenish white color. Found in Roxbury and Dedham; blooms in July.

9. *Tuberosa*—butterfly-weed. Root large, fleshy, branching and somewhat fusiform, but it is only by comparison with other species that it can be called tuberous; stems numerous, growing in bunches from the root, hairy and dusky red; flowers numerous, erect, and of a beautiful bright orange color; grows in Woburn and Newton; blooms in August.

10. *Obtusifolia*—blunt-leaved. Stems erect, supporting a terminal umbel, at a distance from the leaves, which are opposite, ovate, heart shaped at the base flowers large, of a greenish white, tinged with red; it is found in Cambridge and Mount Auburn; blooms in July.

11. *Phytolaccoides*—poke-leaved. A tall, large flowering species, of a delicate appearance; stem erect, four or five feet high; leaves large; umbels nodding, flowers large, petals green, nectaries white or flesh colored; grows in low grounds, blooms in June.

12. *Purpurescens*—dark-flowered. Stem erect; flowers of a dark crimson purple; grows in Cambridge and Newton, but is rare.

13. *Quadrifolia*—four-leaved. A delicate species, growing in dry woods; stem about a foot high; flowers flesh colored; is found in Roxbury and Brookline, and blooms in June.

14. *Veridifolia*—Green flowered. An inelegant species, with small greenish umbels; is found in Leicester; blooms in July.

For the description of the third and sixth preceding species, I am indebted to Dr. Bigelow's excellent work, on the plants in the environs of Boston. There is a beautiful colored engraving of No. 9, and a more particular account of it, in his other most able and splendid publication, called Medical Botany.

15. *Amoena*—oval-leaved. Stalks from a foot and a half to three feet high; at each joint are two large leaves, which are blunt, thickish, stiff, smooth, with purple nerves; umbels rise from the top of the stalk and some of the upper axils; flowers of a bright purple color.

16. *Rubra*—red-flowered. Stem upright; um-

* Republished in Farmers' Register, p. 675 Vol. II.

bels many, from the same common peduncle; a native of Virginia.

17. *Parviflora*—small-flowered. A native of South Carolina and Florida.

18. *Syriaca*—milk-weed, or silk-weed. This species abounds all over our country, and for the many useful purposes to which it may be applied, is deserving of especial attention. The root is perennial, and in April or May throws out, like asparagus and hops, a great number of shoots; the stems rise to six or seven feet in height in a rich soil. When the leaves or stems are broken off, a milky substance, of a viscous consistence, exudes, from whence the plant derives one of its most general trivial names. The flowers appear in July, and are in umbels of from twelve to sixteen on one stem, each containing thirty or forty single flowers, which adhere to the umbel by a long slender stalk, and has a sweetish odor. Each bunch of flowers is succeeded by three, four, and sometimes ten long, flat and rough pods, which enclose numerous round, flat, thin, yellowish brown seeds, wrapped up in a beautiful shining white and soft kind of silk, which constitutes their wings, and by means of which they are conveyed with ease to a great distance by the wind; it has also given rise to the other trivial name, by which the plant is known in some parts of the country.

The great utility of the Syriaca or milk-weed in the arts, has not been understood but since the middle of the last century, although it was introduced into Europe at a much earlier period.

A manufactory of articles from the silk was established in Paris in 1760, and it has long been employed at Louzanne, with advantage, as candle-wicks. Mr. Schneider of Liegnitz, has been distinguished for the zeal he has evinced, in relation to the cultivation and preparation of this article, and has recommended it in two different pamphlets.

In the application of it to paper making, Mr. Schmid of Lunenburg made a variety of very interesting and instructive experiments.

The cultivation of the plant has been found very easy. Mr. Schneider began in 1785, with but six plants, and in 1793 he had a plantation of 30,000, which yielded him 800 pounds of silk the first crop, 355 the second, and 600 the third. They were planted in rows about two feet apart, with a sufficient distance between the roots in each row. The silk was separated into two parts, the longer being used for spinning, and the shorter for hat making and beds.

Mr. Schmid, who was an ingenious manufacturer of paper, made several experiments with the capsules, or pods, which gave the following results:

1. From the interior white rind of the pods he obtained writing paper, pretty white, of good quality, and similar to the silk paper of the Chinese.

2. From the external green part of the pods, a greenish colored paper was made, which, when sized, was stronger than paper made from rags. It was almost as close in its texture as parchment, and even when unsized did not suffer the ink to pass through it. It was excellent wrapping paper.

3. From the bark of the stems he obtained a paper so like, in every thing, to paper made from rags, that the difference could scarcely be distinguished.

The silk when taken from the pods, and being freed from the seeds, is hung up in thin bags in the sun, and when perfectly dry, may be used without any further preparation, instead of feathers, horse hair, wool, or cotton, for cushions, bolsters, pillows, mattresses, and coverlets. From eight to nine pounds is sufficient for a bed, bolster, and two pillows. It is lighter and warmer, when used in forming coverlets or comforters, than cotton or wool, and is nearly equal to eider-down.

For spinning, the staple of the silk is too short, when taken alone, and therefore is combined with flax, wool, cotton, or raw silk.

One-third of this silk, with two-thirds of cotton, forms a very excellent mixture for gloves, stockings, and other articles of like manufacture. One part of this silk and two of rabbit's fur, forms hats exceedingly light, soft to the touch, glossy, and which have a great resemblance to beaver hats.

The plant throws around it, long roots with new eyes; these can be cut off in autumn or early in the spring, before the milk flows, and may be divided into pieces from four to six inches long, which may be planted in trenches, four or five inches deep, in an oblique position, with the eyes or buds standing up.

Where the plant grows wild in abundance, a bed for culinary purposes could be easily formed, from the roots in the manner above described, and would be fit for use the second spring; by which two years would be gained over plants raised from the seed.

Besides the above named articles manufactured from the silk, I recollect having seen, at several of the annual exhibitions of the Massachusetts Agricultural Society, in Brighton, tippets, capes, bonnets, and various other articles, which were very beautiful. They were formed by sewing the tufts of silk by the part which is attached to the seed, to linen, cotton, or silk cloth in rows, one overlapping the other, like the shingles on a roof. They had the appearance of the most delicate and rich fur; and so simple was the work that a child could execute it.

For embellishing the outer borders of pleasure grounds, the skirts of roads, avenues, clumps of trees, the sides of groves, and to intermingle with shrubs, all the American varieties may be used with picturesque effect.

On examining some botanical works since writing the above, I found that Parkinson had received the *Syriaca* from this country, and cultivated it in his botanical garden of rare plants, as early as 1629. He called it Virginia silk, and it was stated that the French Canadians were in the habit of eating the tender shoots as substitutes for asparagus.

It is but little trouble to form in every garden, side by side, beds of dandelions, sea-kale, milk-weed, and asparagus, which, from the last of March, until the green peas appear, will afford a daily and various supply of delicious vegetables. They are all perennial plants, and when once set out, and properly taken care of in autumn and spring, will yield abundant crops, for all time, without removal.

H. A. S. DEARBORN.

Roxbury, March 9th, 1835.

[Judging from the foregoing description, and without the sure guidance of botanical knowledge, we infer that the plant in question is one which we have long known as a very troublesome weed in wet meadows kept for mowing. The only doubt as to the identity of the two, arises from our never having known the weed on dry land. It grew well on a piece of marshy meadow subject to be covered (though rarely,) by high tides, and so saturated with spring as well as tide-water as to be unfit for any thing but meadow. The abundance of the plants, the fruitless trouble of grubbing which they caused, and the remarkable beauty of the silky wings of the seeds, all served to attract much attention at the time—though, as some years have since passed, our recollection may not be perfectly accurate. But what we then deemed the most important quality of the plant, is not noticed in the description above. The bark of the stalk is like that of hemp and flax, and was thought to be superior to either; and even when stripped after exposure through all the winter, possessed so much strength, that we formed the opinion that the plant would be valuable to be cultivated for this product. But its supposed unfitness for dry soils, and the trouble of tillage on wet ones, prevented any action on that opinion. Some of our correspondents who are better informed will oblige us by stating whether this plant is the Asclepias Syriaca, and whether the strength, and fineness of the fibres of its bark, and their fitness for being made into cloth, have ever attracted notice.

Loudon's Encyclopædia of Plants states that plants of the genus Asclepias "thrive best in *peat* or any very light soil." If *peat* in its natural wet state is meant, it adds support to our opinion of the most suitable soil for this plant. The third species named above, *A. Pulchra,* water silk-weed, may be the kind we knew.]

From the Franklin Mercury.

PALM LEAF HATS.

The braiding of these hats is an important and increasing business, which has sprung up within ten years past, and which is doubly valuable in consideration of its moral influence, inasmuch as it offers a remunerating *domestic* employment for thousands of our industrious country women. Few are aware of the extent to which the manufacture is carried on in the country towns. In Ashby in Middlesex county, according to the Yeoman's Gazette, 50,000 hats are braided annually, for which the braiders (more than half of whom are girls and small boys) receive between six and seven thousand dollars. This is not a high compensation for the amount of labor bestowed; but the advantage is that this labor may be bestowed at odd times, and by those who might otherwise remain unemployed. In Petersham and Barre, in Worcester county, great numbers have been made. We have been told that a single commission house in New York, sold hats made in that county in one year, to the amount of ninety thousand dollars. The southern market was for a great while the principal outlet; the sales have fluctuated considerably, and the prices have been gradually coming down. Recently, large quantities were shipped to France and sold readily and with profit, at one quarter of the rate at which the English had been in the habit of selling an article not as handsome, though rather more substantial. The French government have somewhat checked the trade, by imposing a duty of one franc (about twenty cents) on the finer kinds of these hats; the consequence is, that the common ones are now principally sought for export.

In this county the business has been prosecuted to some extent. A dealer in this town, who commenced a few weeks since, has already a hundred and fifty braiders employed. In Shelburne and in other towns we believe that a considerable number are made.

From the Tennessee Farmer.

CURING CLOVER HAY.

As the season for curing clover hay in many parts of the country will probably have arrived, before our number for May can reach many of our subscribers, we have thought it desirable to insert in this number some directions respecting the mode of curing it. We give the course to which we have been accustomed, and add an article from the Albany Cultivator on the subject, which we particularly recommend to the attention of our readers, and we earnestly beg them to test the mode therein recommended, by actual experiment, and to apprise us of the result. If that mode will succeed with us, to the extent described in the article, it is, we have no doubt, greatly to be preferred to the one, which we describe—and that we know to be incomparably superior to the old mode, still practiced by some.

Clover hay should never be scattered out of the swath, because, in addition to the labor lost in scattering and again raking up, the hay is thereby greatly injured. Indeed, if the weather be favorable for curing, neither timothy nor any other kind of hay should be scattered, because, the less any grass is exposed to the sun and air in the process of curing, the greater will be the value of the hay, and the less the labor required.

Let the clover lie in the swath untouched, until about two-thirds of the upper part be sufficiently cured, which, in good weather, will, if the swath be tolerably heavy, be effected in eight or ten hours; if the swath be light, in a proportionably shorter time: when thus cured, turn the swath bottom upwards with the fork, an operation speedily performed. Let it then lie exposed to the sun until the under side be cured, which will be, according to the thickness of the swath, in from four to six hours, then throw three swaths together in windrows, and commence hauling in, the wagon running between two windrows and loading from each. It can hardly be necessary to observe, that all these operations must be performed after the dew has dried off. It is to be recollected, that clover will keep with less drying than almost any other grass. A common test is, to take up a bunch of the hay and twist it, if no juice exudes, the hay may be hauled in with safety—we have often hauled in clover cut in the morning, in the evening, and always the succeeding day, unless prevented by bad weather—sprinkling every layer of hay with salt, at the rate of 12 or 15 lbs. to the ton, or interposing a layer of dry straw, from 6 to 12 inches thick, between every two layers of clover of the same thickness, will be found a great preservative; and especially the latter mode will enable the farmer to put up the hay in a far greener state, than could otherwise be done with safety. Besides this advantage, the straw interposed between the layers of the hay, by absorbing its juices, will be rendered much more valuable as provender, and if salt be sprinkled on the hay, will be greedily consumed both by cattle and horses. From the great quantity of this grass produced on an acre, its highly nutritive quality, the ease with which it is cut and cured, farmers will find, that clover hay is the cheapest food on which they can keep their stock in good order during the winter. If put up in good order in the fall, sheltered from bad weather, and salted, both horses and cattle will keep fat on it alone throughout the winter, without the aid of grain, unless when worked.

The prevalent notion, of the difficulty of curing clover hay, is entirely erroneous. In a climate like ours, there will seldom be found any, in a wet and cool climate, like that of England, the difficulty may exist to some extent, as clover when put in cocks will not resist rain as well as timothy and some other grasses; but in the course of fifteen years' experience, we have seldom lost any, or had it much injured by the weather, indeed we have found it incomparably easier to save clover hay than corn blades, and as three or four tons of the former, with the aid of plaster, can be made at less expense than one ton of the latter, the farmer must be blind indeed to his own interest, who does not take care to provide himself with at least as much clover, as will furnish an abundant supply of provender for his stock.

Clover should be cut for hay when about one half the heads have become of a brown color. If cut earlier, it is believed the hay will not be so nutritious; if later, the stems will have become harder, and the grass be on the decline. For hogs however, and young stock, it will be advisable to cut some so soon as it is in full bloom: when cut in this state and salted, hogs are very fond of it, and it is believed might be chiefly wintered on it, if otherwise carefully protected from inclement weather. At all events, by the use of it as a food for hogs in part, a great saving of corn may be effected.

When the farmer can do it, he will find a great advantage in providing himself with long, narrow, and high sheds, open at least on the south side for the preservation of his clover hay, and when hauling it in, to begin at one end, and spread a layer of hay along the whole length of the shed, and then repeat the same process; by this means, he will be able to put up his hay, in a much greener state than could safely be done, if put either in a stack or mow, and as yet there are but few persons in this country sufficiently expert in the art, to stack it so as to ensure its preservation. In narrow sheds, one load is considerably dried before another is thrown on it, and when the sheds are filled, the narrowness of the bulk being so much greater, there is far less danger of injury to the hay by heating. We again solicit as a favor, from our readers, that they will make full and fair experiments of the mode recommended in the following article, and that they will furnish us with an accurate account of the result; by so doing, they will not only confer a favor on us, but discharge a duty which they owe to the public, for whose benefit it is desired.

From the Cultivator.

MAKING CLOVER HAY, IN COCKS.

Nothing is so hard to combat as the prejudice of farmers, who think they *can learn nothing* in their business. We have often recommended curing clover hay in cocks, as a means of doubling the value of this kind of hay, besides lessening the expense of curing it. Many good farmers and intelligent men, have ridiculed the process, because it run counter to their practice, and was what they could not reconcile to their idea of good management. But they would never make the trial; if they had done so, they would have seen that they were wrong, and we right. We beg leave here to say, that in many districts of Great Britain, spreading hay from the swath, or tedding it, is going wholly out of practice, as causing unnecessary labor, and as diminishing the value of the hay. But there they are not blessed with our ordinary sunshine and heat in the haying season. The hay curing process, with them is a business of some days, on account of their comparatively cool climate and humid atmosphere. But with us, when the grass is matured, and thin, and the weather good, it is often the business of a day. But this cannot be the case with us with early-mown hay, particularly where clover abounds. The grass is then full of juices, and the succulent stalks of the clover require time, as well as sunshine to part with their moisture. Spread and exposed to a hot sun, the leaves, blossoms, and exteriors of the stems soon dry, but in drying, the exteriors of the stems become indurated, and refuse, like wood painted when green, to part with the interior moisture. The consequence is, the grass must either be housed in this half-cured condition, and spoil in the mow, or, if the curing process is completed, so as to prevent damage, the leaves and blossoms, which constitute the best parts of the hay, are over dried, crumble and are lost. Cured in cock, every part of the grass whether the leaves or the thick stalks, dries alike. and is alike preserved, and the evaporation of moisture goes on, I believe, even in wet weather; for a partial, though in no wise a prejudicial fermentation takes place, and the rarified air which it generates, being specifically lighter than the atmosphere, is constantly passing off.

We have been induced to these remarks, at this untimely season, in consequence of finding in the Farmer and Gardener, an agricultural paper published at Baltimore, a communication from John Smith, fully confirming the utility of our recommendation and long practice. It would seem that Mr. Smith was led to make the experiment rather from necessity than from choice. But we will let him tell his own story.

"It will perhaps be recollected," he says, "by all attentive agricultural readers of that paper [the American Farmer] that it was recommended to farmers to put their hay, in its green state, or as soon as cut, into small cocks, and cure it by sweating.

"When I commenced cutting my clover hay the present season, the prospect for favorable weather was flattering, but in a short time it changed, and it became evident we should have a wet spell. I then dropped the scythes and put all hands to putting up the grass (then perfectly green, but exempt from external wet) into cocks of about 200 lbs. cured hay, building them compact and high, to avoid the introduction of rain as much as possible. Rain came on before I secured all the cut grass, but the next day was fair, and I succeeded, by unremitted attention in getting the water dried out of the remainder, and put it up in the same way. It continued rainy ten days, and afforded no opportunity to cure in the sun; the cocks were examined daily, by running the hand and arm into them, and, contrary to all expectation, gave no indications of fermentation. At the end of ten days the weather became fair, the cocks were opened and found to be in a perfectly sound condition, except so far as the rain had penetrated, and the external wetting alone, in my opinion, made it necessary to open it at all. Tell farmers they need not fear losing their hay on account of unfavorable weather at harvest. I have never seen worse weather in hay harvest, and I saved mine entirely well. It is most excellent hay."

Our practice has been, except in cases of necessity, like the one above, to let our hay wilt in swath, that is, to cock in the afternoon that which is cut in the forenoon, and to have the cocks not to exceed fifty to seventy lbs. hay when cured. We are glad to see that a larger quantity will cure well. Let it be remembered that the cocks must not be made by rolling, but by placing, with a fork, one layer above another, till the cock is completed.

From the Genesee Farmer

BURYING BEES.

Mr. Tucker—It is two years this spring, since I first commenced bee-keeping. In the outset, I had no knowledge whatever of their management, and it was a stipulation of the bargain with the person of whom I obtained them, that he should, as occasion required, impart to me such facts as his experience would justify, in regard to their culture. This agreement was satisfactorily performed; and, aided by the information thus received, my success, for a tyro's, was such as to create an almost enthusiastic interest in this branch of rural industry.

In the autumn of 1833, I selected four hives, (double the number with which I commenced,) for wintering. Three of these had so limited a supply of honey, that I was advised to bury them, an operation which, in my mind, was little preferable to throwing them away. But I concluded to "try the experiment," and on one of the last days of November, they were "deposited beneath the little mound," where my mind figured them as possessing the interminable repose of "their last resting place." My absence on "the return of spring," that season when dying worms are wooed again to life, and the faded wing of the insect receives new colorings, beautifully wrought, from nature's dye, prevented me the pleasure of witnessing their exhumation, but the person who took them from their temporary sepulchre, (which was done about the 20th of March,) informed me that on their first introduction to the air and light, their animation was as perfect as that usually exhibited by bees in June. He said that he did not find half a gill of dead bees in all the hives. These hives gave swarms earlier and more frequently than the one that remained above ground, during the ensuing summer.

Last fall I concluded to continue "the experiment" with a single hive. The one selected was very light, probably note containing a sufficiency of honey to carry them half through the winter, had they been kept the usual way. In consequence of a rainy season through the last of November, they were not inhumed until December, probably as late as the 10th. They were occasionally fed in the fall, lest their supply should not be sufficient to insure a subterranean existence. My faith was as wavering when these last were buried, as on the previous winter, and as often as looked at the spot where they were interred, I viewed it as the grave of my little insect friends.

They were taken up on the 28th of March, and much to my satisfaction, I found that the second experiment had terminated with the same happy results as the first. Not two dozen were lost, and new comb was actually formed while they were in their "dark abode."

My "modus operandi" is as follows. A hole is dug considerably larger than the hive, or hives, in every respect. On the bottom of the whole two sticks of three or four inches in diameter are placed for each hive, and on these the floor board, which should be a sound one, is placed. Another board, (two inch plank is preferable,) is put on the hive, and dry straw is as compactly as is convenient placed around it. This, in rainy weather, if the ground is clear from frost, allows the rain to pass freely down, while the space between the blocks furnish a ready reservoir from which it is absorbed by the earth, without offering any injurious effects to the bees. The earth is placed upon the hive in a conical form to turn the water from the hives, the top of which are about four inches below the surface. With respect to the experiment of 1833–4, I cannot say whether the apertures of the hives were closed, but in that of 1834–5, they were not. This experiment succeeded, but whether it is the best way of proceeding I shall not advise.

I regret that I did not weigh my hives, in both instances, previous to burying and on disinterring them, that the amount of food consumed might have been ascertained. But my experiments were both of them faithlessly tried, and unnecessary ceremonies were dispensed with. The quantity of honey consumed, however, was small, as none but very light hives were selected, and their weight in the spring was apparently nearly as great as in the fall. It is my intention in future experiments to mark items more particularly.

In selecting the spot for burying, a dry, and cold, rather than a warm one should be chosen. An individual of my acquaintance buried on the south side of a dry hill. and an entire loss of all thus treated was the consequence. I attributed it, (though perhaps some other defect was the cause,) to such situations being more exposed to frequent freezings and thawings, the insects are subject to more frequent change of temperature, a circumstance injurious to all that comes within its influence. If the situation is such as that the ground will freeze immediately after the trust is committed to it, and remain so until time to "remove the deposites," to me it would appear most favorable.

Yours, etc.

WILLIAM BACON.

Richmond, (*Ms.*) *April* 23, 1835.

From the Richmond Enquirer.

HAIL STORM.

We have accounts of a hail storm, on Monday last, which continued from five o'clock in the evening, to eleven at night; from Fluvanna to Charles City. It came on early in the evening, in Goochland; and its effects in the neighborhood of Dover, on both sides of the river, were most distressing. The hail varied from the size of a hen's egg, to the smallest bird's egg. Some of the stones measured eleven or twelve inches in circumference. On some farms, it has done great injury to the wheat, (already a very short crop,) corn, clover, &c. The damage on one farm is estimated at 5 or 6,000 dollars. We have heard of one farm in Charles City, where the wheat has suffered from the hail which fell in the night.

Extract of a letter from Goochland, dated June 3d, 1835.

"I rode up yesterday to witness the terrible devastation produced on Mr. Sampson's farm, by the hail storm on Monday night. It was distressing to witness it. The finest crops of wheat, corn, oats and clover, perhaps, on James River, totally destroyed. The greatest power of the storm fell on his low grounds, and such was its force, that, I assure you in riding through his wheat field of 60 acres in Sabot Island, I counted from one end to the other, but twelve heads of wheat standing. It was not beaten down, but literally mowed, leaving strong and smooth stubble, and more neatly harvested than I have ever seen a field. Mr. Sampson calculated on a yield from the field of 25 or 30 bushels to the acre. If there are 30 heads standing on the whole 60 acres, it is as much. Mr. Scott, of Manakin Town, who was with us in our ride, stated his and the crop of Mr. Beverly Randolph, to be nearly in the same condition. We, thank Heaven! escaped, but I dread to hear from the tobacco country west of us."

☞ We have not learned the extent of the storm, but we are informed by a stage passenger, that six miles above Wilmington, the hail stones measured nine inches in circumference. Pigs of good size—and many turkeys were destroyed—and, indeed, almost every thing that came in its range.

HAMMERING BY STEAM.

There is no pause, no stop to the inventive genius of our countrymen. A physician of Boston has invented a machine, consisting of numerous hammers which go by steam, the force and rapidity of which will enable the owners of the rich granite quarries of Massachusetts and New Hampshire, to dress and face blocks of this hard rock for building in a very short time, and at a cheap rate. This had been a serious difficulty, and it is now overcome.

From the Boston Transcript.

ICE AND ICE HOUSES.

It is quite warm enough at this present writing to discourse of ice, but whether it will be when the types are giving publicity to the labors of the pen, depends entirely upon the future, which may be noted as a very wise remark. We intend, however, to say a few words of ice and ice houses, that may interest the reader. There are persons younger than ourself who can remember when the only ice sold in Boston, was brought to the city in parcels of ten or fifteen pounds in the box of a market gardener's cart, and sold as a very great luxury at a corresponding price. There were then no ice houses in the vicinity, except a few gentlemen's country seats, and they were built under ground, and were of small capacity. Within the last twenty years the consumption has become so general, and the cost is so small, that ice is no longer deemed a luxury, but one of the necessaries of life. The amount exported also from Boston to southern climates is incredible. The art of preserving the ice is very simple, and in well constructed houses, there is scarcely any loss from dissolution, and it may be preserved for years. We rode out last winter, with Col. Metcalf, of Cambridge, to witness the process of filling one of his ice houses, on the borders of Mystic Pond in Medford, about six miles from the city. The ice house is built entirely above the ground, as is now the well approved custom, even in *tropical* climates. It is 85 feet long, 50 feet wide, and 25 feet posts, and holds nearly 3000 tons of ice. The house is built of pine boards, and the ice is protected from external heat by filling in the walls, which are a foot and a half thick, with the exhausted bark of tan pits—a non-conducter of caloric that has been found perfectly efficacious. The Mystic Pond ice house is very happily located, being so situated that the ice may be discharged directly from the house into the boats of the Middlesex Canal, or the cars of the Lowell Rail Road, and can therefore be brought to the city at much less expense and loss by waste, than from any other establishment. The pond itself is supplied with water from another pond just above it, which upper pond is fed by such abundant springs, that we are told it never freezes in the coldest season. The water, therefore, is of the purest and most limpid quality. Col. Metcalf has lately loaded with this ice a vessel for Rio Janeiro, and another for Bombay. He has also sent freights to Norfolk, Savannah, and other southern ports. It is transported on the canal, and hoisted on board the vessel by machinery, made for the purpose, with great facility.

The process of cutting the ice, getting it from the water, and storing it in the ice house, is ingenious, but simple. The ice house is built on the border of the pond, and one end projects over the water. At this end there are two openings or doors, which extend from the floor to the roof. When the ice has made to a sufficient thickness, say 15 inches, a spot is selected where it is of the purest, most transparent, and solid quality. It is then marked out into oblong squares, 21 inches wide by 3½ feet long. At every 21 inches of width, a groove is ploughed, half an inch wide, and four or five inches deep, by a plough made for the purpose, and drawn by a horse; the ice is then sawed across, at distances of 21 inches, and one series of blocks being removed, the rest is easily set loose by a staff with a broad, chisel-formed end, driven into the groove, and used as a lever. A canal of a corresponding width to the blocks, is then made from the place where the ice is selected, to the house, and the blocks are pushed along with a staff to one of the doors, where it is received into an iron cradle and hoisted up to the requisite height, when a spring, which has prevented the block from falling off, strikes a projection and being forced down, the ice slides into the house, and is there received by persons who push it into its place with a staff. From the commencement of the process to the end, the ice is never touched with the hands. The average weight of each block is about 400 pounds, and being all cut of the same form and proportions, they are packed much more closely in the ice house, or in the hold of a vessel, than when cut out as formerly, with an axe, in a negligent manner.

Extract from the Genesee Farmer.

FERTILIZING PROPERTIES OF LIME.

When the writer of this article went, in the days of his boyhood, to reside in one of the southern counties of Pennsylvania, the land upon which he lived had been purchased at the common price in the neighborhood, £4 Pennsylvania currency, per acre. A short distance to the north-west lay the great limestone valley, that extends, with some abrupt terminations, from New York to Virginia. The serpentine ridge which bounds this valley on the south-east, was considered by the inhabitants as the limits of the grain country; and although the land adjoining it south-eastward was a good sandy loam, it was thought that it would produce nothing but grass, and the land in the valley was then estimated at an average price of £15, or $40 per acre. In a few years, however, the farmers began to haul lime from the valley, and make liberal applications of it on the land south of the ridge. They have continued this process with increasing industry for forty years, with increasing success, and the consequence has been that the valley, which was thought abundantly calcareous without the application of lime, has remained stationary in value, with some fluctuations during the late war, while the land upon which lime has been liberally applied, has advanced from £4 to 80 and $100 per acre, and from the abundance of its crops fully justifies the purchaser.

From the Cultivator.

THE OSIER WILLOW.

The osier willow is worthy a place on every farm, because it takes up but little ground, requires very little care, and furnishes the best materials for baskets, which are indispensable to the farmer. This, like all the willows, is readily propagated by cuttings. Where it has taken good root, its shoots in good ground, grow from four to eight feet in a season. These shoots should be taken off every winter, unless very large willows are wanted, and the number is thereby annually increased. The art of fabricating baskets from them is easily acquired, and may be practised in evenings and stormy days in the winter without cost. For ordinary baskets the osier is used with the bark on; but for neat house baskets they are peeled. The best way to divest them of the bark, is to cut, sort and tie the osiers in small bundles, say early in March, and place the bundles in a pool of stagnant water: and at the season the leaf buds are bursting, the bark will readily strip off.

The osiers may then be laid up to be used when leisure will permit. A well made osier basket is worth three or four made of splits. We have them which have been in wear for years, and are yet good. To give them firmness and durability a good rim and ribs, of oak, hickory or other substantial wood, are necessary.

From the Journal of Commerce.

TEMPERANCE ON RAIL ROADS.

In building the three rail roads from Boston to Providence, Worcester, and Lowell, total abstinence has been the rule with regard to the use of ardent spirits; and it is now the rule for all those who manage the engines and cars on the roads. In building the roads some of the contractors from the first refused to furnish their men with spirit, or permit them to bring it on the ground. It was soon perceived that those contractors avoided all difficulty with their men; that their men did more work; and that although most of the laborers were Irish, the territories of the temperance contractors were so much more comfortable, that they were most popular, and could always select the best hands. The board of directors became so fully convinced of the advantages of temperance, that they made it a condition with the contractors that they should give the men no intoxicating liquor. Coffee and tea were substituted, and cold water.

On all these roads perfect order and decorum have been preserved. Not even the *civil* authorities have been called on to preserve the peace. On other roads where the same description of laborers have been employed there have been repeated murders, endless fights, often with deadly weapons, and the whole territory around has been rendered insecure. The civil authorities have been set at defiance. The military forces, after being harassed by marchings and watchings, have been unable to restore order, and nothing short of the potent finger of a Catholic priest held up before the men, has been sufficient to restrain their infuriated passions. We have no doubt that the difference between the peacefulness of the east, and the riots of the south, is to be attributed chiefly to the difference in the use of intoxicating liquor.

COMMENTS ON FARMERS' REGISTER, No. 10.

To the Editor of the Farmers' Register.

The 10th No. of the Farmer's Register fully sustains the character for utility, so well merited by its predecessors; but it contains many opinions and facts, of which very different views may be taken from such as are presented to us by the writers themselves. Of these I will take the liberty to offer a few, as I have done in regard to the preceding number.

The excellent article on "Dairy Management" although containing many directions applicable to all parts of Virginia where such things as cows, deserving the name of "milch-cows," are kept at all; yet has several that will long—if not forever—prove impracticable for any beneficial purpose.—For instance, the author recommends not only to milk the cows three times a day, but "to have the milk drawn from each cow separately, put into the creaming-pans as soon as milked, without being ever mixed with any other." Now it is quite notorious, that if this were attempted, especially during three parts of the year, on ninety-nine out of an hundred farms, there would be a necessity for substituting small saucers, or vessels of similar size, for "creaming-pans"—each to be carried several hundred yards from the cow-pen to the place of deposite, which is always remote. This transportation, if the cows were numerous, would require several hands to perform it; besides, the nearly nominal milk-woman, whose title, like the definition of the "*lucus a non lucendo*," generally means something almost the opposite of what it would seem to mean. Such a process, to say the least of it, would cost more than it was worth, not to mention the danger that the contents of each creaming-saucer would entirely evaporate before a sufficient quantity could be obtained to make a separate churning—even in a bottle. There is one hint however, that would be particularly useful, and exactly in proportion to the scarcity of milk. It is to let the calves suck *first*, which is no where practised among us. This would leave the richest part of the miserable pittance for ourselves, instead of leaving it, according to the constant practice, for the calf, who is thus treated better than its owner, while its poor dam is often suffered to die of starvation.

Query: Are we to understand your short note on the "locust," as pronouncing the "honey locust" an exotic? I had always deemed it indigenous.*

W. C. Dwight's letter to the Genesee Farmer relative to Hussey's machine for harvesting wheat, is a very interesting communication, and some further information as to the cost, and means of procuring it, would be very acceptable, I should think, to all your subscribers who cultivate wheat.

The history of the horse is a very entertaining as well as useful article; and may, if properly studied, obtain for that highly serviceable animal better treatment than he too often receives from his ignorant and cruel master, who first wears him out for his own pleasure and emolument, and then leaves him to starve to death.

"A Seeker of Light" has asked two stumping questions. The first in regard to "the most effectual and shortest method of restoring to fertility worn, galled, and gullied land;" and the second, to have stated "in specific inches," what may properly be called deep ploughing. Presuming that he would wish to adopt the most economical as well as the quickest and most efficient method, I would say, that the best farmers, with whose opinions I am acquainted, recommend deep ploughing of the arable parts, filling the gullies with small green brush, to be well covered with the adjacent earth, and applying to the surface the freshest and the strongest manure to be procured on the farm.

"Deep ploughing," (as the querist himself says,) is "a comparative term"—consequently, what would be deep in one soil would be shallow in another. A specification "in inches" therefore, cannot be made, unless he will first specify the exact depth of the particular soil wherein he wishes to know what would be called deep ploughing. It may however, be stated as a general rule, that to plough twice as deep as the natural soil, which is very rarely more than two or three inches in eastern Virginia, is deep enough for the purposes of improvement. Even this should depend upon the nature of the substratum; for if *that* be sand, as it very often is, it should never be brought to the surface. Again: in the attempt to plough deep, special care should be taken to lap the furrow-slices, like shingling, and not to turn them completely upside down, which would bring a *caput mortuum* to the top, incapable, for a long time, of producing any thing. Earl Stimson, one of the most celebrated and successful farmers in New York, and one who obtained some years ago, a premium for the best cultivated and most productive farm in the whole state, ploughs only three inches deep, according to his own statement. But all that has been, or can be said of particular modes of culture and depths of ploughing, both require to be somewhat varied according to the peculiar circumstances of each farm. One practice only will be found, I think, applicable to all, and that is, never to plough more than as deep again as the natural soil, but to loosen the earth as deep as practicable with a single coulter, run in the bottom of each furrow, which makes no change in the relative position of the different strata, but vastly augments the capacity of the earth so treated, for attracting and retaining moisture. This is manifested in a striking degree during drought, by coultered corn retaining its verdure much longer than that which had received only shallow cultivation—of which I have seen numerous instances. The practice is, to run the coulter in the bottom of the first furrow thrown from the corn, soon after it comes up, and immediately before the earth is thrown back; then to run it in the bottom of the two next furrows also before they are thrown to the first. This loosens the whole to the depth of some eight, nine, or ten inches, and effectually prevents the soil from baking, at the same time that it secures a soft bed for the young roots to spread in every direction.

On the tobacco article I have very little to add to the numerous, and, (as I think,) unanswerable objections of the writer to its culture. Of this I know scarcely any thing, having never either made or used any. All I will venture to offer in addition to G's very judicious remarks, is a short article from that quaint old fellow, Burton, who, in his most curious work, "The Anatomy of Melancholy," published more than two centuries ago, speaks of tobacco in the following terms:

"Tobacco—divine, rare, superexcellent tobacco, which goes farre beyond their panaceas, potable gold, and philosopher's stones; a soveraigne remedy to all diseases. A good vomit, I confesse; a vertuous herbe, if it be well qualified, opportunely taken and medicinally used; but as it is commonly abused by most men, which take it as tinkers do ale, 'tis a plague—a mischiefe—a violent purger of goods, *lands*, health; hellish, devilish,

---

*We stand corrected in this matter. Ed. Farm. Reg.

and damned tobacco—the ruine and overthrow of body and soule!"

If "I. E. T." will take the trouble to visit any of the gardens in the city of Washington, especially that of Mr. Jesse Brown, the worthy landlord and proprietor of the excellent hotel which bears his name, he will learn a thing or two about the culture of celery that will cause him to change his method entirely, unless he happens to be one of those gentlemen, who, if they can say of any thing—"this is *my* method," will not so much as listen to any other.

The kind of corn recommended by William Carmichael, on Wye, Eastern Shore of Maryland, is evidently the kind lately called "twin-corn" in that state. What he says of Mr. Edward Lloyd's opinion of it makes me *sure* that it is the same.

I agree perfectly with "A Radical" from Norfolk county, as to the fence law; but beg him, and all who think with us on this subject, to bear constantly in mind the old adage, "what can't be cured must be endured." If he can suggest any sure method to rid ourselves of that pestilence, demagogueism, we shall soon get rid of the fence-law grievance; but until then, I deem our case utterly hopeless.

With due deference to Dr. Prout and Professor Autenrieth, I must believe that the new plan of the latter for making bread out of wood! will never be available in any country where either wheat, rye, oats, or Indian corn can be made.—Even on the score of economy, I should say, that our old fashioned bread was the cheapest, to say nothing of the difficulty we Virginians should have in training our grinders to masticate, and our stomachs to digest wooden bread. "Wooden nutmegs" perhaps, has suggested the idea to the learned professor—if indeed he has ever heard of this ingenious American invention. But to make bread of the same article would be carrying the matter rather too far, in any other region than Lapland.

Your correspondent "T. B. A." has drawn a most wo-begone picture of the farming in Virginia on land naturally poor, or, as I have heard it called *"born poor."* Of this kind there are thousands of acres in his country—poor enough, as I was once told an Irishman said of certain hills in Stafford, "to make a rat cry." Bad however, as his picture is, I verily believe that it is literally true, and furnishes a case past remedy, unless by the application, which you suggest, of calcareous manures. But these are attainable only by a comparatively small portion of the owners of such lands. To let them grow up in wood seems to be the only good use to which they could be applied, as their profitable culture is out of the question.

There is one part of his letter where he appears (if he will pardon me for saying so,) less at home. It is the paragraph wherein he propounds a question or two on certain topics of political economy. Had he consulted the most approved writers on this subject, or statistical comparisons of the two methods of conducting internal improvements, by private chartered companies, or entirely on state account; or had he availed himself of notorious facts within our own country, applicable to this subject, I cannot believe that his opinion would have been what here appears. It is well known, for instance, that one of our sister states has tried the latter plan until she has involved herself in a debt of some fifteen or twenty millions of dollars, for works, many of which have been made political party jobs—given of course to incompetent undertakers and superintendents; undertaken sometimes where none should have been attempted; and carried on at an expense far exceeding any that a private company or companies ever would have suffered to be incurred. *They* never, or very rarely indeed, make turnpikes, rail roads, and canals, unless upon the strongest presumptive evidence that they will be profitable to themselves, and of course, advantageous to the public; for the two things, like cause and effect, are inseparable. On the other hand, in a country like ours, which is destined, I fear, to be forever governed by political party under one designation or another, almost all matters of internal improvement when undertaken on public account, are forced to subserve, in locality, in the choice of agents to conduct them, and in the expenditures lavished on them, the popularity of the occupants for the time being, of political power.

One of your own remarks upon T. B. A's. communication furnishes, I think, a strong argument against your apparent preference of the four-shift system to the three-shift system. You call the former "milder;" although you stated that in a certain trial of it for nearly twenty years, "there has been *an actual and considerable lessening of the product.*" 'Tis true you say, "this diminution is supposed to have been caused by the ploughing having been too deep (six inches) for so shallow a soil." But if it was too deep at first, would not the injury have been curing in the frequent reversal of such ploughing during the period mentioned? Query: have the two systems ever been fairly tested and compared by the same persons, on the same soils? All the statements which I have seen, have been *ex parte;* they have been made by the four-shift advocates, and have generally reminded me of a tale told upon a certain jocular merchant of the olden time, who tried to persuade a half-witted customer, that his, (the merchant's) fist weighed exactly *a pound.* The fist of the four-shift advocate has always been thrust into the scale that he evidently wished should preponderate. To try both systems properly, each should exclude grazing; the small-grain fields should be clovered in both, and the manure made on each farm applied in the same manner—say, on the corn land in each. Although the comparisons which I myself have made, have not been sufficiently numerous and accurate to satisfy myself which system is best, yet they have convinced me that the three-shift plan, if pursued in the best practicable manner, possesses two or three advantages which nothing in the four-shift system has counterbalanced—at least in any case that has fallen under my observation. I deem myself an impartial judge, because I really have not "committed myself" (as the politicians say,) on either side. These advantages are, that one-third instead of one-fourth of the land is always producing a grain crop; that the clover turned in for improvement is much more pure, and freer from perennial and noxious weeds, such as St. John's wort, camomile, daisy, blue thistle, and that worst of all pests the prickly nightshade; and that consequently, the three-shift system will produce *probably* as much corn, and *certainly* much more wheat than the four-shift; wherein I have known this latter crop often nearly destroyed by some one or more of the pestiferous plants just mentioned, to say nothing of the far greater increase of insects injurious both to corn and wheat. The farm on which our Trismegistus Col. John Taylor, of Caroline lived, and on which he pursued the four-shift system, was excessively annoyed before his death by these nuisances. But when I first knew it, some forty odd years ago, then under the three-shift plan in its worst form, and before he owned it, not a thing of the kind was to be seen. Several gentlemen who have followed the rival system have often complained to me of the constant diminution of their wheat crops. Of this, there was *no doubt*; but whether to ascribe it to the redundant accumulation of unrotted vegetable matter; to the greater increase of destructive insects; to the more rapid multiplication of the noxious weeds already enumerated, to which I might have added the still more formidable enemies—running-brier, trumpet flower, yellow locust, sassafras, and persimmon, they did not undertake to assert. Now, if the four-shift advocates, *versus* three-shift advocates, admit the foregoing facts, which can be established beyond cavil or refutation, let the non-committed farmers and planters decide between them. How this controversy originated, seems to me of no importance; but its continuation surely need not be long, if only a few reputable farmers would undertake to try the rival systems fairly. The friends of each have taken for granted *that* which both Flemish and Chinese husbandry, 'tis said, have proved to be untrue. This is the necessity for resting land—in other words, leaving it uncultivated for some years. Both in Flanders and China, unless my information be incorrect, all arable land is made to bear some crop every year, and its fertility is at least preserved, if not increased, by the application of manures and a proper rotation of crops. Why might it not be so in Virginia?*

The article on draught from the "Library of Useful Knowledge" is an excellent one, and should be diligently studied by every person who owns either a plough or a carriage of any kind, since the principles on which they ought to be constructed in order to render them as perfect as practicable, are probably as little understood as any other art can be, which is of such great importance to mankind.

"A" has presented some very useful hints on the management of sheep, which in most parts of Virginia are worse treated than any other other stock, although as profitable, perhaps more so, in proportion to first cost, than any other. In summer they are rarely noticed, except to shear, or to furnish a lamb for the table; and in winter, too often left to shift entirely for themselves.

COMMENTATOR.

*The "four-shift" rotation referred to above is that recommended by Arator, of corn, wheat, and two years' rest, either with or without clover—and not the very different rotation called also "four-shift" of three grain crops with clover fallow. Each system has its peculiar disadvantages, (which we do not mean to discuss here—) but the latter "four-shift rotation" is truly such as "Commentator" advocates on the authority of Chinese and Flemish practice. There is *no year or season of rest*—but the fourth crop (clover) is turned in as part of the manure necessary to bring three grain crops in succession. As to Arator's four-shift rotation, of which we have had long experience, however beneficial for restoring lost fertility to poor lands, it is certainly liable to the objections stated above, of encouraging the increase of troublesome weeds, and destructive insects—of both which evils we have had woful experience. As to the causes of diminished production in our experiment of this rotation, referred to above, we can throw no additional light on the remarkable results. Ed. Farm. Reg.

COMMENTS ON FARMERS' REGISTER—No. 11.

To the Editor of the Farmers' Register.

Mr. C. W. Gooch's two letters contain much interesting and valuable matter. It is therefore to be regretted that he should have blended with it any thing as a settled truth or principle, which is still a subject of controversy among some of the best writers, both in this country and in Europe. Such are his assumptions as to the cause of "Malaria," and the best state in which to cut grass for hay, which he says, is *"in full bloom."* Without expressing any opinion myself on either topic, I will here only remark, that it cannot probably be unknown to Mr. Gooch, that numerous well written treatises have been published within a few years past, on the causes of malaria, maintaining not only different, but contradictory opinions, and that the subject may truly be said to be *"adhuc sub judice"*—yet undecided. Again, it is quite improbable that Mr. G. should be ignorant of the statement made by Sir Humphry Davy in his Agricultural Chemistry, of the ninety-seven experiments made by the Duke of Bedford's gardener, at Woburn Abbey, for the purpose of ascertaining at what particular stage of growth it was most advantageous to cut the different kind of grasses subjected to these experiments. The number of grasses subjected to trial was ninety-seven, and in most of the cases, as well as I recollect, the quantity of nutritive matter ascertained by accurate analysis, to be contained in the grass cut when the seed was ripe, exceeded the quantity in it when in flower, to an enormous extent. Quere, does Mr. G. use the term "grass-knife" as synonymous with grass-scythe, or is it a new implement?*

His suggestion to mix two kinds of grass-seed together, is probably a very good one, and might be extended to the mixture of three or four, if we may believe some late English publications on artificial grasses.

The description which he gives of what his neighbors have called "blue-grass," renders it

*The term was meant for the scythe, it is presumed, as it is often so applied in this part of Virginia.—Ed.

highly probable that it will prove very valuable in lands similar to those on the Chickahomony, although it is to be regretted that a different name had not been bestowed on it, since we already have a highland grass by the same name, and of quite a different character. If this new grass "will conquer the bull-rush," it will accomplish more than any other species has ever yet done among the various trials I have seen made. Effectual draining however, most certainly kills it.

As to two other pests which he mentions, the running brier and the sassafras, I have had woful experience of both, but have not succeeded in extirpating either, although his mode for destroying the latter is certainly worth trying.

The method of sowing grass seed recommended by Mr. G. is by hand. This I know is the customary mode; but not comparable to that by a machine made and sold by Sinclair and Moore of Baltimore. This is so constructed as to sow any kind of small seed, or small grain, broadcast, in spaces twelve feet wide, and as fast as a horse can walk. Small tin slides, perforated with holes of different sizes, regulate not only the quantity of seed distributed by each step of the horse, but also enable the sower to change the kinds when he pleases, merely by moving the slides backwards or forwards. It is likewise admirably adapted to sowing gypsum. The cost I believe is about 60 dollars; the construction simple; and the durability probably great. In level open land, I have never seen any method of sowing small grain, grass seed, or plaster, that seemed to be comparable to sowing them by this machine.

From Mr. G's remarks on what he calls "*the guinea grass*," I should infer that he means a species of millet which I have heard so called, but improperly. This inference I draw from the fact that Mr. G's opinion is in direct contradiction to that of the only farmer of my acquaintance who has cultivated the guinea grass to any extent. The gentleman is Mr. John Roane of King William, who has been trying it for some years, and speaks so highly of it both for soiling and hay, that he is now extending its culture. Mr. G's conclusion against "exotic grasses" altogether, because *some* of them have yielded but "one crop of hay," seems neither very logical nor accordant with the experience of many other farmers. It is notorious, for instance, that the lucerne which is an exotic, can be cut four or five times in the season at the average height of fifteen or eighteen inches—and I myself know an instance which occurred last summer, (dry as it was,) of guinea grass being cut four times, at the average height of at least three feet, in each case. Mr. G. inclines to the opinion, once universal in my part of Virginia, and in favor of which more, I think, can be said than the scoffers at it are aware of—I mean the occasional, if not the annual burning of lands which are much covered with dead grass and weeds. Without either denying or affirming it to be correct, I will barely add the admitted facts in its favor. It converts coarse vegetable matter—full of the seeds of weeds and the eggs and larvæ of insects, into the fertilizing substance, ashes, which is free of all these nuisances; and it lessens much the labor of preparing the land for an after crop. To this may be added, as something worthy at least of being well considered, whether certain discarded practices in agriculture have been condemned upon sufficient evidence of their worthlessness. The individuals of each generation are too apt to consider themselves the peculiar "children of light," in comparison with their predecessors, and consequently sometimes discard, as unworthy of their superior knowledge, practices superior, in some respects, to their own. So it *has been*, and I fear *will be*, to the end of time; but those who think so, should still not despair of guarding some against so pernicious a fallacy.

The second letter of your correspondent Mr. Gooch, increases much in value as well as interest, for it has more facts and fewer opinions. Among the former, I find several which furnish in my humble judgement, some very strong proofs in favor of applying manures *in the freshest state*, and *to the surface*, instead of ploughing them under. They also favor, as I think, the opinion, that what we call "*resting land*," is needless, if a proper rotation of crops, and manuring were regularly pursued. There is however, *one* fact—at least stated as such by Mr. G., which I myself, although probably as old a man as he is, and living also in the tide-water portion of Virginia, have never witnessed. I mean that wherein he states that "between the Chickahomony and James River hills, there are portions of land, with a gray and ash colored soil *of nine or ten inches thickness*, resting on a clay foundation." Now, I, as well as Mr. G., have examined most soils—such as may properly be so called, in the tide-water part of Virginia, and I have never seen a single spot of highland, where that which could truly be called *soil*, was *five inches deep*. This difference of opinion however, resolves itself into a question of what is really *soil*? and will be deemed perhaps unimportant by my readers—especially as I accord with Mr. G. in the opinion, that it is very advantageous *gradually* to mix with it a portion of "the red clay foundation," wherever it can be reached, even by trench ploughing.

I regret that Mr. G. has not given us the produce in bushels of potatoes, turnips, and oats which were made in the several experiments which he states; for by this omission he has deprived his statements of fully half their value. In the oat case of more than half. Why should he fear that we would doubt his word in the latter case more than in any other which he states—evidently with a confident expectation of being believed? I believe that I know the gentleman personally, and if all your other correspondents are equally worthy of credence, your paper has none more trustworthy, where facts are concerned.

His experiments with the two twenty-acre fields merit particular attention—especially for the fact furnished by the latter in favor of top-dressing with fresh manure. It is high time that farmers should come to some settled opinion, and adopt some uniform practice in regard to this important process. What a deal of labor, expense, and time, and manure also, would be saved by discarding your costly stercoraries—your short and long muck deposites—as well as all the complicated variety of compost heaps requiring ten or twelve months to form them, and three or four horse ploughs afterwards to turn them under—if it were once satisfactorily ascertained, that the best state to use manure was when freshest; and the most judicious mode of applying it was on the surface. Query—have we not already more experiments and facts in favor of this last opinion than against it?

What Mr. G. has told us of coal ashes trials, is not sufficiently particular; for "*other manures*" having been used after them, we have no proof of the share, (if any,) which the ashes had in fertilizing the land which was treated as he states.

Upon the whole, I think your subscribers have much cause to be pleased with both Mr. Gooch's communications, although he has given us something like half a dozen prophecies at the close of the last, which, I fear, can have very little effect in stimulating to more industry the numerous drones of the present generation—since, upon the most moderate computation, they will require some century or two for their fulfilment. This may discourage rather than excite; for if Virginia cannot thrive until then, her case is hopeless. Look at them, I pray you, sir, and then say whether my fears are well or ill grounded. First, the final "improvement of the Roanoke." Second, the same thing accomplished for "the northern extremity of the great Valley beyond the mountains. Third, "the cis and transmontane region nearest Fredericksburg, having easy access to it." Fourth, "the great central improvement of the James and Roanoke, with its lateral branches, offering the Richmond market to the Ohio country, and East Tennessee." And fifth, though last, not least, "a line of rail roads and steam boats connecting the extreme north with the extreme south of the Union."

Mr. Dupuy's inquiries and suggestions relative to "sheep husbandry," involve questions in political economy of considerable interest to Virginians generally, but particularly to land-owners in the middle of the state. There are very few subjects connected with agriculture, of which we are more ignorant, although during the prevalence of the Merino mania in our last war, there were more discussions, and more pamphlets—to say nothing of newspaper out-pourings, than enough to elicit all the information on the subject that the United States and Europe put together could possibly furnish. Why it should have evaporated, it is no easy matter to say; especially when matters were then carried so far, that not only men's politics, but their patriotism, were measured and graduated by their zeal and efficiency in raising sheep—particularly if they were Merinos.

The article which Mr. Dupuy has noticed in the "Cultivator," must be, I suspect, justly attributable to some remains of the old "Merino mania" in the writer; for if land worth one hundred dollars per acre, can really be more profitably used in raising *sheep*, than in providing food for *men*, it will prove indisputably, that in the arithmetic of such political economists *a sheep* is intrinsically worth more than *a man*. To this, as a universal maxim, I cannot strain my credulity; although (by the way) had I a right to make the exchange, I would require but little, if any boot, between some men of a certain political creed which shall be nameless, and an equal number of good sheep.* But every thing like *badinage* apart, (which with some of your contributors, seems to be deemed a contraband article in so grave a thing as an agricultural journal,) I will state, in compliance with Mr. Dupuy's request, notwithstanding it is apparently confined to "northern friends," some odds and ends of information picked up by myself, on this subject, among the Merino patriots of our last war. *One* of them who had profited largely from the fever, by selling his Merinos to the infected, at enormous prices, assured me that he had never found, after various and long continued trials, any cheaper or more effectual way to secure the health of sheep, so far as that depended upon medicine, than to give them tar with their salt. His method was to pour the former into a long narrow trough, made for the purpose, and then to stir up with it a quantity of fine salt, sufficient nearly to fill the trough. The mixture being inseparable, the tar was always eaten for the sake of the salt, and would last a considerable time without the trouble of renewing. As to their other treatment, the information which I collected from him, as well as many others, may be summed up in the following particulars. That although sheep *will live* without any other food than that which they can find for themselves, provided they have sufficient range to hunt it out, yet that they cannot be made either very good, or very profitable, without strict attention to feeding them well during winter, and the month of March, with corn-fodder or hay: to keeping them dry and clean, under a proper shelter, during all rainy or snowy weather—to separating the ewe lambs from the ram, until the second season after they are yeaned—and to regular salting at least twice a week, all the year round. There are numerous well authenticated facts to prove that sheep thus kept will yield, on an average, about seven pounds of wool each; whereas if they are neglected, as usual, the average will rarely exceed one and a half pounds. In regard to minor points, the majority of good sheep farmers whom I have consulted, recommend that ram lambs should be castrated within a few days after they are yeaned; that they should not be sheared until the second season: that this operation should be performed on them, as well as the older sheep, immediately after the long season in May; that a mixture of tar and fish oil should be smeared on from the end of the nose along down the spine, to the root of the tail: and that the flock should be kept rather in highland than lowland pasture, but occasionally changed from one field to another, and penned only in dry weather, during the months of May, June, September, and October.

There are some few of Mr. Dupuy's inquiries that I cannot answer, but hope that some other person will.

Mr. J. Du Val has given your Matthews correspondent with the queer name, a very proper rebuke for violating, as he seems to have done, his own advice, and in the very letter too, containing that advice. I agree perfectly with Mr. Du Val

---

*Our editorial pen was in hand to mark out this passage, as touching upon the forbidden subject of party politics. But it escaped erasure upon the ground that each reader would agree to its truth as to the party to which he is himself opposed—and that thus, by rare luck, an opinion might be expressed in which all parties could concur.—Ed.

and yourself, that it is best in general, for every writer to sign his own proper name; but there are two obstacles very hard to overcome, real diffidence, and false modesty, which is but another name for pride. Which of the two operates upon myself, I must leave it to others to infer from what I have already written, if they cannot hit upon some better motive. However, should the spirit move me hereafter to continue my communications, I mean at some future day, seriously to repent of former anonymous scribblings, and to give you, as well as all others whom it may concern, my proper appellative.

W. G's remarks "on harvesting corn," will guard all rash experimentalists from adopting the process recommended by Mr. Buel and Mr. Coleman. In their climate, where the dwarf and flinty varieties of corn are the only kinds cultivated, and where they have plenty of hay for their stock, the method may answer. But in a large portion of Virginia, wherein corn is a very important staple, consisting almost entirely of those mealy varieties which are comparatively late in ripening, and therefore requiring more sun to fit them for housing; varieties, too, that constitute the chief, in many cases, the sole dependance for supporting our horses, cattle, and sheep by their fodder—the practice of cutting up the entire plant at the season proposed, would render all the fodder nearly worthless, and would cause, (as I myself have seen on several occasions,) much of the grain to become mouldy in the heart.

That stripping the blades and cutting the tops might be beneficially delayed much later than usual, I have no doubt; nor have I any that it would be advantageous to discontinue it altogether, on every farm whereon a sufficiency of hay could be made to support the stock.

The short article "on splitting fire-wood" reminds me of a very important fact communicated to me by a good practical farmer several years ago. He stated it to be his practice, founded on his own experience, as well as that of his father, to saw through the heart of every stick of timber which he used either for gate-posts or the sills of houses. This, he said, caused them to last much longer, and I have often since, seen his assertion verified. Only a few days ago I was walking near two old gate-posts which had stood ten or twelve years in the same spot, and happening to think of the above fact, I examined both. The sap part was sound for some depth from the surface; whereas, the heart, which would certainly have lasted the longest if split, as we see by fence-rails, was so rotten, that I thrust my cane down into it almost to its head. The cause of this I cannot conjecture, unless it be, that the heart containing more pyroligneous acid than the sap, and this acid being confined by the surrounding wood, which soon loses, in the seasoning process, its own portion of this principle of decay in wood, the centre decays first because the acid in it cannot escape.

The remarks of "Agricultor" on yoking oxen, furnish another strong case to be added to the thousands already recorded, all going to prove how very slow all agriculturists are in either seeing, hearing, understanding, or believing that any practice whatever can possibly be better than their own. Common sense would lead us to conclude that whatever older nations than we are, universally or generally do, in any of the arts differently from ourselves, must be at least worth trying: but common self-conceit or sheer laziness says *no*—and hence the snail-like progress of all improvements in husbandry.

Whilst our agricultural societies are offering premiums frequently for things, which to say the least of them, are of very doubtful utility, why could they not proclaim one for the exhibition of a pair of oxen yoked according to the Spanish mode? To this might be advantageously added another for the exhibition of a horse shod after the French and German method, which has been said by very competent judges, to be far preferable to our own.

"A Planter from the Lower James" has given us some useful hints on "wheat-seeding." Permit me to add a few more on the same subject. For opening water-furrows in wet land after the wheat is sown, no single mould-board plough can perform it well without running backwards and forwards, which always makes the furrow so wide as to waste land; whereas, the double mould-board plough made by Sinclair and Moore of Baltimore, opens it of the proper width, and at one stroke, thereby saving half the time. To open water-furrows on high, dry land, which, when done at all, is always performed by a plough of some kind or other often running twice, a preferable plan is to use the single coulter, with two small mould-boards about five inches long by four wide, nailed on the helve some four inches above the lower end. This goes deeper than any single-plough, and makes the narrowest furrow compatible with the object.

For hauling off corn, the best kind of carriage which I have ever seen, is one called "a flat" in some parts of the country. The advantages are, that it carries much more than any cart; that it is loaded by men standing on each side, instead of having one to stand on the cart-wheel, and another on the top of the load; and the wheels being eight inches broad and about three feet high, they rather benefit the wheat by rolling the land, than injure it by cutting the beds, as the cart wheels always do, particularly when the land is wet.

To make these "flats," requires very little mechanical skill. The plat-form, or bottom is made like the bed of a cart-body, but longer and wider. It has neither sides nor end-boards, and is covered with thin, smooth plank or boards, nailed on length-wise. In front there are three strong upright pieces about two by three inches square, and five feet high, inserted in the front sill of the plat-form, and connected by one cross-piece at top, and another about three feet below. A similar frame is fixed behind, but made to take off, while the load is forming. This is done by throwing the corn-stalks—ears and all, cross-wise from the sides—the ears in the middle, and the loaders standing on the ground. The hinder frame is fixed when the load is nearly complete, after which, a rope or common grape-vine is fastened to the centre of the front frame, and passing over the load to the hinder frame, secures the whole. The unloading is much facilitated by placing under and over the load a rope or vine long enough for two or three persons to hold on behind, after the removal of the hinder frame, while the "flat" moves on in an opposite direction. This kind of carriage is also far preferable to a cart or wagon for hauling in wheat from the harvest field.

The wheels are made either by sawing off rollers eight inches thick from the body of a tree, if you can find one large enough, or by fastening together either with large pins, or cross-pieces of iron bolted through, three pieces of timber three feet long, and twelve by eight inches square. To these, when thus fastened, the circular form is afterwards given, and boxes of a suitable size fixed in the centre of the middle piece. A single box to go entirely through each wheel would probably be better. If it can be deemed worth while to lighten the wheels, this may easily be done by striking two circles—one four or five inches from the centre, the other, thirteen or fourteen inches from it, and hollowing out the middle space to a thickness of four or five inches.

To guard wheat against smut, it has been ascertained by very numerous and well attested experiments, that nothing more is necessary than to steep the seed in strong brine, and after taking it out, to mix with it as much quicklime as will adhere to the wet grains. A few hours after this it is fit to sow: but the seedsman must use the precaution to grease his hands occasionally, or the lime will soon make them very sore.

Pray, Mr. Editor, tell me what your correspondent means by "*gripped*" land? Excuse me for asking, and pardon my ignorance; for although somewhat curious in regard to provincialisms, and a great hunter up of such odd things, I have never seen nor heard of the above term before, and can neither guess nor imagine from its usual acceptation, what its figurative meaning can be. This puzzle has prompted me to make another request, which is, that you will exercise your "veto power" against all future provincialisms unaccompanied by proper explanations.*

Mr. D. Chandler's mode of cultivating asparagus is, without doubt, a very good one; but the distance one way, at which he plants, is greater than usual, and therefore more, probably, than enough. It may however, be judicious, where land is scarce, as he makes it produce also a crop of beets the first year. "The proper distance for this vegetable" he says, is to have "the rows two feet apart." Is there not a very needless loss of land in this? I have often seen the roots four or five inches in diameter when grown not more than twelve or fifteen inches each way. Mr. Chandler's article furnishes *another proof* in favor of using "fresh unfermented manure" in preference to any other.

The report in favor of a geological survey of our state, and the act which resulted from it, has brought to my mind a subject which has often excited in it, the most melancholy reflections. No state of the same age, is more in want than ours, of internal improvements of every kind; nor any which is susceptible of a greater number that would pay large profits upon the money invested in them. Yet few, comparatively speaking, have been undertaken, and of these it would not be easy to point out a solitary one which has been managed in the best practical manner. The cause, the most deplorable cause of this failure can readily be found by any Virginian who can summon courage enough to examine impartially, facts that must mortify his state-pride. Such examinations will inevitably lead him to the discovery, that party-spirit and favoritism have constantly been permitted to manage nearly the whole affair, in every case. Instead of invariably employing men to superintend and execute the work, *solely* on account of their talents, knowledge, skill, and experience, all these have been either made secondary considerations, or have been disregarded entirely; and some miserable partyism or other, has *in reality*, although never avowedly, been made the test of qualifications. This has resulted in part, from the circumstance of all our works having been made too much a matter of state concern, from which every body knows it is impossible, in these times, to exclude party-politics, rather than to leave their management entirely to the judgement of the private stock-holders. Ask any member of our legislature for fifteen or twenty years back, I care not who it may be, whether he has, in every case, voted for the best qualified individuals in the whole circle of his acquaintance, to fill the various public appointments in the gift of the legislature; and if he does not reply in the negative I will suffer myself to be called a slanderer of my own state. If it would not be too invidious I could state hundreds of cases to prove the truth of my assertion. But I will forbear, and will add nothing more than a solemn warning to all who are immediately interested in the great James River improvement about to be commenced, not to suffer this destructive curse of party-spirit and favoritism to mar the chances of success, by governing the appointment of the engineers and other agents who must be employed

---

* A "Grip" is a small ditch cut across the beds after the wheat is sown, and every other operation has been completed. The grips pass through all the low places in the water-furrows, (or trenches between the beds—as "water-furrow" is a provincialism—) and serve to draw off all the rain-water that would otherwise stand in puddles, and injure the crop.

It would be gaining an important object if our agricultural nomenclature could be made so general and uniform, that there should be no necessity for either using or explaining provincial terms. But under present circumstances, it is difficult to know what would be considered as provincialisms requiring explanations, and what terms are of such extended use that the explanations would be quite unnecessary.

"Grips" are described by another writer at page 106, vol. I. We have before proposed what we think would be the best means of avoiding the difficulties of using provincial terms in agriculture—which is, to collect and publish as full a list as possible of all the provincial agricultural terms used in the United States, with the definitions and the localities stated. If this was done, we suspect that our friend "Commentator" would be surprised to find that several of his own terms were considered by other persons as provincialisms. We should be glad to have his aid (and no one could furnish better,) in preparing materials for such a glossary. Ed.

to conduct it. The company have got a charter which I will venture to say can never be executed without several important amendments; and they have got among their members personal partialities and preferences (very honest ones I have no doubt,) which will interpose serious obstacles to success. Add to this, there are some *local* interests working against them, under the plausible guise of public spirit, and therefore the more likely to injure them. These remarks, I assure you sir, are not designed to discourage, even if I were vain enough to believe I possessed any such power. But my sole motive is, a wish that the great work may succeed; and take my word for it, that I do not speak unadvisedly, nor without some good cause in offering the foregoing cautions.

"American Filberts." If by this term be meant the foreign nut raised in the United States, I assert, from long experience, that they will succeed perfectly well in all the tide-water portion of Virginia—perhaps in every part of the state, and bear abundantly; although the bushes are sometimes killed by an insect that adheres close to the bark of the bodies and limbs, and resembles small, hard scales.

The article from the "New England Farmer" on "clover," is particularly recommended to the consideration of disputants about the three and four-shift systems. If it be "*good economy always to sow clover with small grain, though it is to be ploughed in the same or the next season,*" and we have this writer's authority for it—if moreover, "its value to the next crop cannot be less" (as he also asserts,) "than quadruple" the cost and labor of sowing the seed—then have we a complete answer—at least in my opinion—to the strongest objection to the three-shift system.

The recommendations from "the Cultivator" of "root culture" and "pruning fruit trees" in June and July, deserve particular attention. Without the former, as well as meadows or grass lots, we cannot supply our families with the requisite quantity of milk and butter, unless at a great expense of winter feeding with grain and fodder; nor can we have either beef or pork of our own raising, but at great extra and needless cost. In regard to pruning, the writer has omitted one essential operation, which is, to smear all large wounds over with some one or other of the various compositions recommended by gardeners.

Of Gov. Barbour's address, it is nothing but sheer justice to say, that it calls our attention, in very appropriate and forcible language, to several matters of the deepest interest to every true friend of his country. What could be more patriotic than the establishment of a Professorship of Agriculture at our University? What more mortifying and heart-sickening, than the neglect—nay, the fatuitous reprobation with which it has been treated? What epidemic—what pestilence has ever raged in our country, that has proved more destructive to the bodily health of our citizens, than the "party and political and office-hunting strifes," of which he speaks so feelingly, have proved to their moral health? Among all the evils growing out of this state of things, there is none, I think, greater than the utter neglect, on the part of our legislatures, of the vital interests of agriculture, from the establishment of our union to the present day. They did *once* crawl so far, several years ago, as to appoint a "Committee of Agriculture!" yes, verily, a "Committee of Agriculture!" If any doubt my word, let them search the journals of the House, and they will assuredly find, that this patriotic effort was actually made, and as far as we can judge from the circumstances of the case, with "bona fide" intent, on the part of the performers, that they were actually achieving something which would redound in no small degree, to their own honor, as well as to the benefit of their state. What has been the result? Can a single man be found in our whole state who has even known, or even heard of a solitary act of this committee—unless it be of a negative character, since their establishment? In fact, they have literally done nothing, unless it is to furnish the inexplicable phenomenon of the legislature of a state, whose *predominant interest is agriculture*—a legislature, too, consisting *chiefly of agricultural men*—not only neglecting utterly, *all agricultural interests*, but actually making a mockery of them, by creating a committee to take care of them, which has literally proved a sinecure appointment. God save poor old Virginia! (for nothing else can,) when the maddening business of president-making, for ever kept alive by demagogues and office-hunters, is constantly withholding her citizens from studying and providing for all those vital interests by which she lives, and moves, and has her being!

In your editorial comments on "the recent enactments of the legislature of Virginia, affecting the interests of agriculture," I entirely agree, except in your approval of the conclusion to which the committee of agriculture arrived in regard to the petitions for changing the present fence law. Your own reasoning on the subject is evidently founded on the erroneous supposition, that the petitioners sought "*a sudden and entire change of policy.*"* In this I am perfectly confident you are mistaken, for I myself was one of the signers, and conversed often with many others on the objects of the petition. Not a man—at least in my hearing, ever said a single word in favor of a precipitate repeal. On the contrary, all expressed an opinion similar to yours, that the change which they sought—like all other changes of a general

---

*Our words were intended to be applied to the view of the subject *professed* to be taken in the report of the committee of agriculture, which is only applicable to an entire and radical change—and not to the objects of the petitioners. We are well assured, (and would have so said in these remarks, it it had been deemed necessary,) that the object of the advocates of a change was generally such as our correspondent states. Our concurrence in these views, and the decided opposition to the principle and policy of the present law, have been sufficiently expressed. But for a change of any ancient law to be beneficial or permanent, it is necessary that it should be preceded by a decided change of popular opinion. Ed.

and long established practice, should be made "*slowly, but surely.*" The petitioners wished only to abolish the system, and designed—as in all similar cases, to leave the choice of the details, as well as the time and manner of accomplishing their object, to the good sense and judgement of the legislature. But admitting the rejection of the petition to be perfectly right, did the committee determine justly in abstaining from any attempt whatever to amend the law, merely because they deemed it wrong to repeal it altogether? Was there a man in our whole legislative body who could conscientiously say, that the present law is faultless? Nay, can a single person be found in our whole community, by whom the law has been read at all, who will not pronounce it full of most glaring defects—defects too, that might very easily have been remedied, without disturbing its precious principle of taxing enormously the whole agricultural portion of our people for the imaginary benefit of a few owners of comparatively worthless stock? If there be any such man, it has never yet been my lot to meet with him. As to that part of the committee's report which you so truly designate as "miserable and false reasoning," I will not trust myself to speak of it as I think it deserves.

COMMENTATOR.

From the [British] Quarterly Journal of Agriculture.

ANIMALIZED CARBON, A NEW MANURE.

This substance is of French origin, and its manufacture is secured by patent. It was discovered by a French chemist; but that it is a substance easily manufactured may be inferred from the fact of its being shipped free on board for 35s. per ton. Mr. Joseph Owen, of Copenhagen, acquired the knowledge of the manufacture from the patentee in France, and has since established a manufactory on his own account in Copenhagen. His traveller, a Danish gentleman, was the first to introduce this new manure to the notice of the Scottish agriculturists. We have not had an opportunity of seeing a sample of it, but it seems it has been tried last year by Mr. Dalgairns of Ingliston, and Mr. Inches of Cardean, who, we hope, will favor us with their opinion of its efficacy. We understand that the Danish gentleman has disposed of 250 tons of it in the counties of Forfar and Kincardine. Mr. Owen's card gives the following account of its nature, and the mode of using it:

"The chief excellency of this manure is, that it is powerful in its effects, occupies but little room, is easily separated, and conveniently used either by hand or drill; its effects are farther to ensure a rich crop, by gradually ameliorating the soil, and rendering fallowing unnecessary. For wheat, rye, buckwheat, barley, and similar descriptions of corn, about 8 cwt. 1 qr. 16 lbs. is used per acre: it may be either broadcast or drilled in before harrowing. For flax, hemp, beet, potatoes, &c. about $10\frac{1}{2}$ cwt. per acre; and 12 cwt. 2 qrs. 10 lbs. per acre for artificial meadows, different sorts of cabbage, rape, culinary plants, and for refreshing natural meadow land. For plants that are set in rows, a handful is put to each plant; for those which are transplanted, a child follows the planter and throws a very small handful of the manure into each hole, which is immediately covered over with earth; in several places for rape, it is scattered out in rows along the roots of the plant, which the plough covers by forming a new furrow. On meadow land it must be spread out in December or January, when the snow is not on the ground. Generally speaking, it is well to mix the manure with half its quantity of finely sifted earth; but there is no necessity for pursuing this method. On light and warm soils about 2 qrs. 22 lbs. less per acre is used than on cold or clay lands, where an extra 2 qrs. 22 lbs. are added to the quantity as beforehand directed to be used; it is in fact left to the farmer's judgement to make use of the above directions, according to local circumstances. What characterizes this manure most is, that it developes its effects so slowly and gradually, that it may be applied without danger in contact with the seed or roots of plants; in this it differs from a number of other manures which are less rich, but more heating. In Scotland it has been tried in 1834 on eight different soils, has been found nearly equal to bone-dust for turnips, and has since been ordered in large quantities from the manufacturer, Mr. Owen, at Copenhagen, who delivers it free on board at 36s. per ton.—*Ed. Qu. J. A.*

[We have seen in the last year's numbers of the *Annales de l'Agriculture Française*, several notices of the manure referred to above, but none so full as to show how it is prepared, or of what it is composed. The following, however, may throw some additional light on the subject. The remarkable cheapness of the article, of which the English editor speaks, may be perhaps caused by the adulteration which is here made known.]

REMARKS UPON A FALSIFICATION OF THE ANIMALIZED CARBONACEOUS MANURE.

Translated for the Farmers' Register.

The great demand for some years back of animal black, and of the charcoal which is left by the sugar refineries, has determined some persons to speculate on these manures, and to increase their quantity by the addition of matters having a like appearance, but a less value, and containing neither the blood, nor the other matters, which make the base of these two manures. It is important to cultivators to know these fraudulent mixtures, and nothing is more easy, especially in relation to the black earth of Picardy,* which is the most used in these falsifications, and which is now transported for this purpose to Brittany in heavy cargoes.

To prove the existence of this fraud, it suffices to sprinkle a little of the manure in a shovel, to heat it red for some minutes, and then to let it cool. Then if the manure was pure, the ashes left on the shovel will have an uniform grayish color. If it contained the *black earth*, the ashes will present reddish, or rust colored particles, which will be the more numerous in proportion to the quantity of the admixture of black earth. * * * * *

---

*This matter, designated also by the names of *black ashes*, and of *pyritous ashes*, is met with in abundance in many localities, particularly in the department of Aisne. It is composed of argil, (or fine clay,) sulphuret of iron, sulphate of iron, of coally and bituminous organic substances. Steeped in water, it gives an acid solution, which strongly reddens litmus paper, (or vegetable blues.)

[A place is given to the following article because it is in reply to one already printed in this No. (p. 79,) and which was inserted principally on account of the remarkably heavy products promised by the writer, from his new mode of culture. We are enough inclined to distrust all such large promises—but the high recommendations with which several of our editorial brethern introduced the former article, gave it, apparently, an additional claim to attention. It is however treated with any thing but respect in the following reply—and our readers may judge for themselves as to the comparative weight of the opposing statements. The tone and manner of the reply, will serve to show with what "scant courtesy" some of the northern farmers are accustomed to treat each other, in the discussion of agricultural subjects.

From the Farmer and Gardener.

POTATOES.

American Hotel, Baltimore, May 19th, 1835.

Having an errand in the office of the editor of the Farmer and Gardener, I had handed me, the 1st No. of the 2d vol., containing an essay of Mr. A. K. Barnum, of Vermont, on the culture of potatoes, which the editor recommended as being worthy of my particular perusal: accordingly I read it, with some attention.

Perceiving the writer to be a theorist, one who aimed at creating an excitement, and that he had contradicted himself; and knowing from my own experience, that his piddling mode, as he has been pleased to call it, is deviating from known and well established practice, and fearing that if permitted to go without refutation from some one, it would be liable to lead many an innocent farmer astray from the true principles of the culture of this valuable vegetable, to their damage, as well as prove a loss to the community, after a more careful perusal, I gave the editor my opinion in full, that the author was not a practical farmer, and that very many profitable remarks could be, and ought to be, made, in order that people should not be misguided.

The editor insisting on my communicating my objections in writing on the subject, I consented, on the ground that he should be connected in my remarks with the author, he having given his opinion strongly in favor of his principles of culture and still persisting therein.

In the culture of the potato, it is necessary to know the nature of it, with respect to its growth, what are its elements, and what its constitution; that is, what it will bear without injury, it being a most delicate root, and what mode of culture is necessary to ensure the most desirable and abundant crop.

I have found by experience, that the potato is not particular as to its choice of soils, or its usage as to manure. It will thrive well on high and on low grounds, in ordinary seasons, if there be no extremity of wet or drought during their growing, and will generally produce a reasonable and satisfactory crop, entirely without manure, but are sure always to repay for extra attention.

The potato above any other vegetable is found profitable to cultivate on new rough ground, among stones and roots, where the ground cannot be sufficiently worked for any other crop usually cultivated, until time and labor renders it more pliable. Here the farmer is greatly benefited in the culture of this crop, as the potato is more peculiarly adapted to rough, half cultivated, grounds than any other crop, and the cultivation, by the more frequently working of the ground, tends to the better subduing of it. The farmers to the north, besides bringing their rough lands to, avail themselves of the certainty of escaping from the evil of the ravages of the worms that so often destroy a crop of corn, by first planting their new swarded ground with potatoes, and it is well to observe, that this swarded ground is far the best for a crop of potatoes. We generally plant to the north ground newly broke up, once with potatoes, and once with corn, and then sow it down to grass and grain.

This mode of culture is of well known and uniform practice. As much ground as a farmer wishes to till is taken up yearly, that is by two years planting it, and managed in this way. Thus it becomes necessary to plant as many acres of potatoes at least as the farmer wishes to take up yearly, for the benefit of stirring his land, and keeping it loose, by distributing his manure in proportion to the land required to be taken up for the benefit of his grass, as well as a proper system of tillage. In this mode of husbandry he does not use the *line*, clear out his walks, nor shovel over his land into beds; but he has use for all his manure for the benefit of his three crops, and to fit the ground for grass. On Mr. Barnum's system, it will take all the manure a very economical, industrious farmer can possibly procure on a considerable farm, to manure one acre, for he recommends spreading and manuring high, the first coat to plough in, then to drill, 20 inches apart with a plough, not less wide to be sure than 8 to 12 inches, and four deep, and in those furrows two inches thick, the first coat requires from 25 to 50 bushel cart loads, the latter will require 50, aggregate 75, this will take all the manure of a good farm. He says there is great benefit to be derived in this mode of using manure from the coming crop. Well may his neighbors say let him piddle with his line, &c.

But above all his deviations from rational farming, is his providing heaps of different kinds of earth, from different situations, near where he plants, to hill his potatoes with; this it seems is not intended as manure, but merely for hilling, as though there was not earth enough: if this last process was to benefit as manure, according to his theory, all the worth of it would soon be evaporated; again, there will be an abundance of weeds and grass, and every foul kind of vegetation before the potatoes are as large as he hills them, which would form a complete turf, and be almost as high as the potatoes; how are these disposed of? We hoe them as soon as they appear, when the potatoes are but a few inches high, or we are punished for longer neglect: how does Mr. B. lay his weeds? they are by his plan sure to get quite large, and very numerous, by the time potatoes are budded.

This doctrine is contrary to all usage, in all my acquaintance in my own state, New Hampshire, New York, and Pennsylvania, where I have lived and farmed it. By the time potatoes are budded for bloom, if nothing be done from planting to that period, a little dirt or compost around the potatoes, would avail nothing towards a crop, it would serve to nurse and nurture the weeds only, and would not benefit the potatoes at all. But if this compost or dirt is used as manure, why not spread and harrow it in, immediately, before the virtue escapes by evaporation; for much of the virtue of manure passes off in this way in a few hours exposure to sun. In his first manuring he is anxious to prevent this effect; but I would ask what becomes of his economy of his manure in the latter application, it being exposed for months to the influence of sun and rain? I conclude, therefore, that Mr. B. is inconsistent with himself.

Notwithstanding the potato will bear poor and indifferent treatment, and produce a crop on any soil, rich or poor, high or low, and with but slight care and attention, (I do not mean not to hoe them at all) it is nevertheless, the most delicate of all plants cultivated. It suffers sorely from the least changes of weather, that is from wet to dry, or from heat to cold, and soon yields to frost. A little too much wet when first planted will cause them to rot in the ground, and if up, a slight inundation will cause them to wilt and die; and if a change from cool and wet to warm and dry, they are much affected, and from dry and warm, to sudden wet, they are also much affected, especially at a time when near maturing, when they are sure to give up; and this is the cause that potatoes are so often not good, having failed to become matured; and let me remind the farmer that all vegetables, at this stage, are in their most delicate state. This is the time too when we are in danger of our grain blighting, and the time it is most frequently blighted, if at all, from sudden heavy rains; and from these causes we had not half a crop of potatoes in New Hampshire the last season, and those but half the usual size. The potato is easily cultivated as I have shown; and they will well repay for good usage, both in manure and good hoeing. I would as soon slight my corn as my potatoes. Mr. B. recommends planting potatoes four inches deep; my experience teaches me the contrary. If I plant low ground, I plough my ground in beds, in a direction for the water to drain off, then harrow lengthwise of the furrows, and the small lands; having a number of these, side and side, I take a light sharp horse harrow, and harrow crosswise of the beds, which pulverizes the ground, and fits it well for planting, leaving a small space between the rows, which answers two purposes, one for a guide for the rows for dropping; this is done by dropping in the middle of the tracks of the harrow, which is easily and correctly performed, by any small boy. It also serves completely to fill up all cracks or holes, the seed lying fair and easy. I then drop my manure directly over the seed potatoes, and when covered up, the seed is safe from inundation, by being some inches above the surrounding surface: the seed lies warm under this manure, the rains drain into the middle furrows. Thus I do not lose a hill when those that *hole* four to six inches for the hill even on common high ground, lose much of their planting.

Another great advantage is derived from this mode of planting, above the great increase of yield, it prepares the ground for a crop of grass.

There are other great advantages from this mode of culture: I plant about three feet distance, it takes the most of the surface that is pulverized to cover the potatoes, and by the time they are twice well hoed, my hills are as I want them to be. They naturally rise high above the surface in form of a sugar loaf; this hill is to turn off heavy rains, and it naturally keeps the potatoes from being too moist, as they are often injured thereby. In harvesting, I find a great advantage in the manure being above the level; the hills being peaked, render them very easy to harvest, and the manure is advantageously mixed with this loose surface over all the ground, taking care to harvest each row by itself, hauling the mixed loam and manure in one direction. This mode gives a rich surface over all the ground, and with a little harrowing, it becomes as smooth as an onion bed: by improving this opportunity it availeth much. This ground is sown in grass, if I choose, in the fall, if early, and it is fitted to sow conveniently in the spring, on the snow, if I choose, or otherwise. This mode of planting potatoes for the benefit of grass, is I think preferable to Mr. B's. mode.

I have obtained what I call very large crops in this way, say one of the most favorable dry seasons, on some portions of the best of the piece, from five to seven hundred bushels per acre, but no average like this. But the influence that the different seasons have on this kind of ground is very great on the crop. Some cold wet seasons, as above, the potatoes on the same kind of ground, have hardly been worth harvesting. I have ascertained in my latitude, 42½, when at home, that potatoes yield best planted shallow, that is, if manured in the hole, to drop them on top of the manure, instead of under; they have thus in some cases, produced double the quantity of those planted under it, in the same kind of holes, made side and side. It is most safe to make the hills as peaked as they can be, conveniently, to cast off the water in heavy rains. It is certain, from experience and observation, that potatoes are more often affected from the superabundance of wet than by drought, and in an average of seasons, therefore, it is wise to guard against the greatest evils. It is not generally known that potatoes hold out and grow best if they lay dry in hills; on the contrary, if the hill be wet through, and continue to be kept wet, it so affects them as to cause a dropping of the leaves, which is called the rust, and they will continue faltering without the possibility of a remedy, in any subsequent stage whatever, if but half grown, as to the root.

Mr. B. prescribes a rule for planting potatoes; I cannot, myself, venture on so invidious a task as to fix a definite rule in a case where its propriety is to be determined by contingencies. The season and soil are so variable, that they render a general rule somewhat imperfect. But I will say, for strong moist ground, well manured, seed high for a large crop: sometimes we may seed too high on quick land, if it be a dry season. But the distance the hills are to be apart is a consideration. I have found that three feet each way is the most proper distance to ensure a good crop, and potatoes of a handsome size, for table use, &c.

Taking this for the distance on the rich prepared ground, as I have described, three common sized potatoes to the hill will be more profitable than any less quantity. It is no use to cut them on such ground. If they should be cut small, the vines come up small and weak, grow fast and fall down, and on such ground the vines will run over the ground and keep green until harvest. I have often found some few ripe, and some in the same hill small and green, and generally very ill shaped, whereas on the same ground with the same culture, seed high with good sized potatoes, planted at the same time, they come up strong and are sure to stand erect, will shoot out their young at the same time, and will grow near of a size, ripen altogether, one or two months earlier, and will be found of suitable size for table; this is the mode that I recommended to obtain the largest crop and far the best potatoes. I have tried every method, even the piddling method of Mr. B. as to distance; it ruins them for a crop, to sow them in the way he has described, and much more in the size.

I once tried an English mode warmly recommended to produce 900 bushels to the acre: it was to prepare the ground and drill two feet apart, and plant the seed lengthwise, the potatoes in contact with each other. They were well attended; the result of the crop was, as any agriculturists would judge, there was after the rate of 900 bushels found on the acre, but the time of finding them was not at harvest, it was when I planted; they produced nothing worth harvesting.

It is observable that Mr. B. speaks of the importance of sun and air in his first mode, as described, as though they were the principal causes operating to produce his large crop when in his latter method he produced his largest crop, though he precluded sun, air and light, from entering into his beds. Where they are sown but one foot apart, if they grow at all, there will be a bed of vines, and if they are kept clear of weeds, as they must be to produce any potatoes; and here too, he omits the great essential of hilling, and yet he gets the largest crop without this very essential and heavy work of hilling, with at least two hundred loads of compost manure to make his hills with, did there ever before, such a wild notion enter any man's brains as to think of hilling potatoes in this way; and can any agriculturists suppose there ever was a good potato produced in this unnatural method? I will also notice his expressions, that are still wilder: he says he did not mean to be understood that 1,800 bushels could be raised by field culture, but now says that eight hundred to 1,200 can be raised upon a single acre, easier than half that crop on four acres, and with less expense. This account implies that he had asserted that 1800 bushels could be grown on an acre, and he surely meant in his new mode of culture. Why does the writer cringe and keep back what he pretends he has done, or said? Not one bushel does he assert, in positive terms, that he has ever raised in any mode of culture; and there is all the reason in the world to suppose that he never did raise a bushel by any culture whatever. But why does he hope to be spared from the shafts of the critic? Because this is a dream of his and he has by relating it in this public manner, caused the excitement that he tells of—an excitement extending even to the four corners of the world—and now he is afraid that he will be questioned on the subject, and dreads lest he should be asked if he ever raised one bushel of potatoes in his manner of culture. I will observe another grand mistake of his, which every practical farmer will readily detect him in—that potatoes planted in neighboring fields of different varieties, are so fond of each other, male and female, and their connection is such that in sending off their farina to each other, by the aid of soft breezes, they lose their caste, and become impure—and this he states is the cause that they so often degenerate.

It is certain that every practical farmer very well knows, they never degenerate by crossing in the least, even if they are planted together in the same hill. It must have been corn that he had heard of mixing from such causes, and I apprehend, being quiet unacquainted with the potato and its culture, he has confounded one plant with the other.

The gentleman to be sure, has stated some important facts, with respect to the manner of harvesting potatoes so as to preserve their qualities long. There is great propriety, as he says, in harvesting them with but little exposure to sun and air; and his manner of binning and turfing them over tight, is highly proper; but I cannot see why the spade or shovel, that the turf is cut and handled with, would not do to beat it down with, instead of a wooden mall. I would rather and what I have said heretofore on the subject, that is, that the sun and air soon generate a poisonous action in the potatoes; so much so, that it is well known that many a noble animal fed on them have died; this has taken place where potatoes have lain in out buildings exposed to the air for a long time, and the animals have been constantly fed on them. The same potatoes, if cooked and eaten by men, would be sure to give them a degree of sickness, if not unto death. If we determine to have good potatoes and to keep them so, they should be harvested by night, or in a cool overcast damp day, and picked up immediately after the hoe, and kept close in a body, entirely excluded from air, and go into the cellar as moist as they came from the hill, and the more moist dirt adhering to them the better. These potatoes will not vegetate the next season to injure them any before the next crop. There is another remark of the writer's which has much correctness in it, that is, that the potato thrives best within the latitudes described by him, and that they grow to greater perfection, and are there of a better quality. This, no doubt, he has been well informed of. This essay would be lengthened quite too long, were I to enter into a minute detail of each objection I have: my desire has been to correct erroneous principles so that farmers should not be misled to their injury.

I will only add, that the distance I have chosen for my hills, is derived from my experience in the culture of potatoes. At this distance, they have a good share of sun, air and light; they also have good space for roots, and strength of ground, so that they will mature a good crop, and if seeded well with whole potatoes, or good sized pieces, they will be found of good and even size for table use, and well ripened in good time, in ordinary seasons.

Varying from this rule, in planting the common large field potato at a greater distance, it tends to an inconvenience in hoeing, as to an easy way of hoeing, over all the ground, and dividing and making a proper light peaked hill, which renders them easily harvested. If on the other hand the distance be reduced, an inconvenience is experienced in hoeing, and shaping of the hill, and an interference in the growth, is very perceptible; the size being reduced in proportion to the distance.

In seeding the potatoes, they should be placed close together in the hills, by which means they are easier worked, give more room for sun and air between the hills, and are more readily gathered when ripe in the fall.

ABEDNEGO ROBINSON,
of Portsmouth, New Hampshire.

P. S. I will further observe, that although the potato of different varieties are so near alike, yet it is a fact that the sun and atmosphere vary in their effects upon different varieties; proving poisonous to many kinds, the white, most of all of them; yet there are some of the colored varieties that those elements have a salubrious effect upon; the long red potato is much improved by spreading them open to sun and air for a few days, especially in the spring. They will become a little wilted and dried, but are nevertheless rendered very pure for eating, and in my humble opinion far preferable to any within my knowledge. There are some other colored ones that will bear sun, but will not improve like those named.

While on this subject, it will be but justice to the state of Maine to remark, that while I have been visiting the middle and southern states, I have observed that all the principal cities, and villages, seem to be almost wholly supplied with the best large potatoes from that quarter. Those most highly esteem ed are called here the *Mercer*, in New Hampshire they call them Shenangoes. This variety sells uniformly for 25 cents a bushel above all other varieties. Notwithstanding the abundance exported from Maine during and since the last fall, her supply seems still unexhausted; which circumstance alone must satisfy every one of the adaptation of that state to the culture of this greatest vegetable friend of man, and of the productive quality of her lands. I must be indulged in the remark, that it is enough to astonish any person to behold the quantity, size, and beauty, of the potatoes, which we see daily carted and drayed through the streets of the southern cities—and which readily find a market at from a dollar to a dollar and a quarter per bushel.*

From the Edinburgh Quarterly Journal of Agriculture.

ON THE PRESERVATION OF POTATOES OVER THE YEAR.

[In the 1st vol. of the Farmers' Register, (p. 213) we gave a particular account (translated from the *Journal d'Agriculture etc. des Pays-Bas,*) of a mode of preserving potatoes for several years, the principle of which is like that of the following, the exclusion of heat. It is strange that so simple a process has not been more extensively used in places where potatoes form an important article of culture and of food.

As the best mode of preserving potatoes until the produce of the next year's crop should be brought into use, is a matter of considerable importance, I beg to refer to vol. XXII. p. 135, of the Transactions of the Society for the Encouragement of Arts, &c. where is detailed the following method adopted with success by M. J. De Lancey, Guernsey.

M. De Lancey says: "early in March, 1803, I observed my winter's stock of potatoes, which I had dug in October, 1802, sprouted from the mildness of the weather in this island. I accordingly took indiscriminately from my pile about three dozen, and in my court-yard dug a hole two feet and a half deep, under the protection of a south-west wall, where the rays of the sun prevail for a few minutes only during the day, at any season of the year. Then, with three pantiles, one at bottom, I laid most of my potatoes in the hole, and placed the other two tiles over them in form of the roof of a house. They not containing all, I threw the remainder carelessly into the hole, (having no great confidence in my experiment,) covering the place over to its usual level. Business calling me home during part of the summer, I neglected looking after my small deposite; but, on the 21st January, 1804, nearly 11 months after covering them, I had the curiosity to examine them, when, to my astonishment, I found them, (two or three excepted, which were perforated by the ground worm, though firm,) all perfectly sound, without having in the least vegetated in any respect, fit for the purpose of sets and the use of the table, as I have boiled a few, and found them similar in taste and flavor to new potatoes. I further pledge myself that they were perfectly firm. I have still some of them by me for the inspection of my friends, who all agree that they are so."

In another letter, dated 17th May, 1804, M. De Lancey says: "I avail myself of the opportunity of a friend going to London, to send three of the potatoes, as a confirmation of their being fit for sets, as they are actually sprouting. The potatoes I send I pledge myself are of the growth of 1802." Then follows the certification of the Secretary to the Society of Arts: "the above potatoes were examined before a committee of the Society on the 30th of July, 1804, and found to be in a state fit for vegetation."

From the above experiment, it is evident that *vaults* or *deep trenches*, out of the reach of atmospheric influence, would effectually retard the growth or sprouting of the potatoes during the period of about *twenty-one months;* that is, from the time of taking up in October, till the 30th of July in the *second year*, or say at least *eighteen months* —and we have here a period of time three times longer than would be sufficient to fill up the interval betwixt the old and the new crop of potatoes.

It is probable, that potatoes for deferred use, say from April to October, would be more safely deposited in January or February than at an earlier period; for it cannot be doubted that when just taken from the field, they possess a succulence and moisture rather inimical to sound storing in large quantities, besides which the examination and removal of damaged sets would contribute much to the security of the deposited heaps. If we can preserve ice from melting, we can surely keep potatoes from sprouting; and the latter is undoubtedly an object of much greater importance than the former. Trenches or vaults would probably re-

*This estimate of value, is entirely too high—the wholesale price of eastern potatoes, during the fall, when they are brought to market, ranges, as in quality, from forty to sixty cents per bushel. We presume our correspondent must have allusion to the retail price in the markets, and not to any sales in quantity. Mercers in the early part of the spring were high, and probably by retail, in the markets, brought the maximum price as named.—Ed. Farm. and Gard.

quire three or four feet of covering of mould, besides all the advantages that can be gained by selection of a situation not less exposed to the sun; and if the potatoes deposited were formed into breaks or divisions of five, ten, or fifteen polls, [bolls?] according to circumstances, with intervening partitions to prevent the access of air, there is little doubt, that by well contrived and well constructed vaults or trenches, potatoes may be kept in excellent condition, from the beginning of April till the end of October for domestic purposes, as well as for the use of horses and cattle.

G.

From the Alexandria Gazette.

STATE OF THE CHESAPEAKE AND OHIO CANAL.

A continuous canal is now open for navigation 110 miles from the basin, in Washington, to eight miles above Williamsport.

The entire cost of the canal, including all expenses, estimated at $4,200,590.

The canal from Georgetown to Little Falls is 80 feet wide at the water line, and 7 feet deep; and to Harper's Ferry averages fully 60 feet in width and 6 in depth, from the point of eight miles above Williamsport it is reduced to fifty in width and six in depth, and will retain the same proportions to Cumberland.

There are no obstructions on the canal to prevent the free passage of steamboats; the only permanent bridge being at an elevation of 17 feet above the water line.

There are 52 locks, and the elevation of the canal as far as completed is 353 feet.

There are five aqueducts, all constructed of solid masonry, and 136 culverts.

The canal is fed by five dams. They are constructed on the most approved plans, of the best materials, and give promise of great strength and durability.

Engineers are now locating the line of the canal to Cumberland.

Experiments are now being made to test the practicability of navigating the canal with steamboats. As yet nothing definite has been ascertained, but the directors do not despair of ultimate success.

From the Norfolk Herald.

THE PORTSMOUTH AND ROANOKE RAIL ROAD.

The great usefulness of this road to the inhabitants of Southern Virginia, is becoming more palpable every hour. We learn that the road has been completed as far as "Murfee's Depot," in Southampton County, (or, rather two miles beyond it,) distant 42 miles from Portsmouth, to which point the cars pass daily. On Friday last, 60 or 70 bales of cotton from the farms of Mr. Newsom and Mr. Vaughan, of Southampton, were received by the road in this borough, and immediately disposed of. We farther learn, that a considerable quantity of cotton is at the depot, and will probably be brought down before this paragraph is put to press. It gives us pleasure to state, that 60 packages of goods, addressed to the merchants of Southampton, were forwarded by the rail road, on Saturday last, to their place of destination.

GYPSUM AS MANURE NOT INJURED BY BEING HEATED.

To the Editor of the Farmers' Register.

Henrico, May 29th, 1835.

In a late No. of your Register, I endeavored to obtain information whether "gypsum submitted to the action of a red heat would lose any of its fertilizing qualities." From your editorial remarks in reply, I felt satisfied that the chemical combination of the lime and sulphuric acid, was not affected by the heating process. Under this impression, I have subsequently made a trial of it on a small scale. If you should consider a statement of the experiment of any importance, it is at your service.

Agreeably to the instructions of my employer, on the first day of April last, I applied gypsum to a considerable portion of clover of one and two years old, at the rate of between three pecks and a bushel to the acre. At the same time, I took promiscuously from a heap of lump gypsum several pieces, weighing in the whole 77 lbs. These I had carefully heated to a red heat, when they lost rather more than 25 per cent. of their original weight. It was given to three of the plantation hands, who in little more than fifteen minutes prepared it for sowing—it then filled a half bushel measure slightly heaped. I applied it to a ridge of clover situated between two ridges which had unburned gypsum applied to them in the same proportion, and on the same day and without any possible difference of the soil. The benefit derived from the application of the gypsum has been highly satisfactory, nor does there appear to be the slightest difference in the benefit resulting from the burned and unburned gypsum. So far as this experiment has gone, though on a very limited scale, I feel satified that the great fertilizing powers of gypsum are not impaired by heating, while the process of pulverizing it is greatly facilitated.

I consider the heating of gypsum to a degree sufficient to dispel its proportion of water, a good test of its quality, and consequently, of its value as a manure. Gypsum which loses, on being heated, from 25 to 30 per cent. of its weight, I think may be considered about the best quality for manure. If, on heating, it should lose less than 25 per cent., I think it highly probable that it contains some foreign substance, which would lessen its fertilizing qualities, and of course, render it of much less value.

Gypsum presents considerable variety and diversity of appearance, and with the view of ascertaining whether any real difference existed as to quality, I selected a few pieces, on which I tried the effects of heat. The following are a few of the results:

1st. A piece of gypsum of light blue color, texture hard, having an oily or greasy appearance, lost, on being heated to a red heat, 26 per cent. of its original weight.

2nd. Do. of a white color, interspersed with veins of a reddish brown—texture very hard, presenting much the appearance of marble—lost 23 per cent.

3rd. Do. of a dull white color—spotted with bright red and gray, having cavities lined with transparent crystals. Lost only 17 per cent.

4th. Do. of a dull white color, with light blue spots; texture very close and hard. Lost rather more than 22 per cent.

5th. A quantity of manufactured gypsum bought in the barrel—lost 20 per cent. An equal quantity manufactured at home from pieces of the above mentioned varieties—lost rather more than 24 per cent.

Should the heating of gypsum be considered as presenting a test whereby to ascertain its qualities, it would appear from the above, that gypsum presenting the appearance of the first mentioned specimen, is the best for manure—allowing that that which contains the greatest proportion of water, which I believe seldom exceeds 30 per cent., is of most value. But in presenting you with the above remark, I beg not to be understood, as positively affirming, that such is the case—though I think it highly probable. I trust however, that some one of your readers may be induced to make the experiment on a larger scale than I have an opportunity of doing, and whose chemical knowledge would be adequate to present more satisfactory results, than my limited experience of that important science to agriculture enables me do.

A. NICOL.

[The experiment reported above is interesting, and its result may lead to much saving of labor in preparing gypsum—and thus enable the farmer to avoid the frauds of some of those who grind for sale. We have made a similar experiment this spring, and in like manner found equal benefit from the gypsum prepared with, and without heat. But in this case, the burnt gypsum was perhaps more finely pulverized, and therefore the fitter for immediate effect: and we should require longer time, and more trials, before deciding positively. The practical result however, is just such as theory (directed by knowledge of the chemical composition of gypsum) would have indicated, though in opposition to the generally prevailing opinion. (See remarks on this head at page 603 and 631, vol. II.)

The water chemically combined with gypsum is in an unvarying proportion—which is 22 per cent., according to the now received opinion. [*Rogers' Guide to Geology.*] Therefore no more than 22 per cent, of weight could be lost by driving off the water alone from the purest gypsum—and the excess of loss, above that proportion, shows that this test (at least as used by our correspondent,) cannot be relied on, except perhaps for comparative results. He lost more than the water chemically combined in every trial but one. This excess of loss might be of additional water held by absorption, (as a hard brick would,) if the gypsum was very pure: or if adulterated with chalk, or any calcareous earth, and the heat was strong enough, the loss would be still more increased by part of the carbonic acid being driven off.]

For the Farmers' Register.

HERDS GRASS ON SALT MARSH.

In answer to inquiries made by a farmer in your 12th No. on salt marsh and meadows, I can say for the last five years I have had several acres of such land well set with red top, or herds grass. The ground is subject to repeated overflowings, both spring and fall, and many times the tide-water from the Sound has been so much impregnated with salt as to leave a white scale or scum of salted matter all over the earth, and on examination I have found it quite salt to the taste, but without its causing any apparent injury to the grass. Apprehending injury from these annual overflowings of the ground with salt water, I had the land the first year enclosed with an embankment to prevent inundation, and through the centre a three foot ditch was cut with a flood gate at its mouth to let off the fresh water not needed, at low tide, and to keep out the salt water at high or storm tides. This answered very well while it lasted; but the first severe gale from the north-east swept away my dam, and the tide-water took complete possession of my meadow. To my disappointment and gratification, I discovered but slight injury to the grass, and in a few days it had a more deep blue and flourishing appearance than before.

The land, before sowing the grass, had been well broken up, and planted two years in corn—but without success—it being too wet and cold, and subject to bugs, for that crop. On preparing the land for the reception of the grass seed, it was laid up into beds of six feet wide, having a small water furrow between each, leading to the main ditch; that the water either from tide or rain, may be more readily conveyed off the ground. Equal proportions of timothy and herds, with half a pound of red clover seed was sown to the acre. The timothy has nearly disappeared, and no clover is to be seen, having been entirely overrun by the red top, or herds grass. The seed was sown the 1st of October.

I have the last year made a small trial of gama grass on such land, and have reason to believe it will succeed and produce an abundant crop of good hay. I find it best to set it on ridges two and a half feet between, and six inches distance on the ridge. The gama I find, on the rotten shell and black sandy loam, to far exceed in rapidity of growth any grass in our part of the country. The seed should be sowed in the garden, kept clear of grass and weeds the first year, and transplanted the first of March in the meadow.

J. B. MARSH.

Beaufort co. N. C. May, 1835.

"STUMP AND BARREL LEGISLATION"—FENCE LAW.

To the Editor of the Farmers' Register.

Fairfax County, May 7, 1835.

I received your No. 11 yesterday, and am indebted to "Commentator" for a sound and hearty laugh, which ended in my referring to your 9th No. in which "Jeremiah" was backed by "X. Y. Z." who showed by plain arithmetic, what "stump and barrel" legislation cost upon 640 acres of land per annum. Now what more shall I do to save my beloved Virginia? Shall I sell that which I have and give it to the poor, and follow the "general assembly?" Will it not suffice that I pay under the command of this high and learned body $220 per annum for confusing, confounding, and commingling my rights with those who claim only to depredate by the authority of the "general assembly?" Did they never read that Moses, who was a bond servant in Egypt, commanded the people by the highest authority, that "they should not covet nor desire other men's goods?" Why should we violate this plain honest command? Are we less than the slaves of Egypt? What am I to say of your much boasted modern schoolmaster? Your great political institutions? Am I to go back and say, as was said of the "beginning," that "darkness dwelt upon the face of the deep?" When I ask in the power and right of justice, why mock me? Why give me a stone when right and justice demand bread? I care not so much for my own rights—but why, in the name of heaven, should we make men familiar with the violation of each other's rights? Why hang a man for the violation of a strumpet, the stealing of a horse, &c. &c., and yet solemnly say he may drive ten thousand hogs upon me to root up and destroy my young timber, grass or grounds? I am not disposed to be disrespectful to the general assembly. I bow to the majesty of the people; but as a free man I shall dare to complain of injuries, come from what quarter they may.

We are professedly a christian people. It is commanded that we should not covet, nor desire other men's goods—yet many good men, who would tremble at the thought of being daily violators of the law of God, are scrupulous and tenacious of carrying out their rights as derived from the general assembly under the fence law. Who will openly say that the principle is unsound which gives to every man that which is his? Sir, I venture to say, that you will not find one in a county: yet I read in the newspapers that many have lost their elections for being suspected of partiality to this command of their Saviour—in plain English, for their love of upright law and exact justice. Are men aware of the dangerous tendency of this unrighteous law? Do they see that in breaking down the strict principles of moral law and christian usage, they are slowly and insidiously giving sanction to Agrarian distribution, and a diabolic scramble for property? Let the moral aristocracy sleep a little longer—let the rust of universal corruption enter a little deeper, and the devils themselves will weep over our fate. The holders of property may then "sleep on," for their hour will have come. I am aware that politicians will avoid this subject as they would a *boa constrictor*, or a rattle snake. To whom then am I to appeal? Sir, I make it to that portion of society who in my youth I have so often derided—I mean the christians. They are, and must forever be the salt of every civilized society—their pure morals and straight upright rules operate like a cement, and sustain the various and complicated machine of government: and that holy principle of their master that "ye render unto Cæsar the things that are Cæsar's," they dare not reject.

JEREMIAH.

Translated for the Farmers' Register from the *Annales de l'Agriculture Francaise* for February, 1835.

LACTOLINE—DESICCATED MILK.

In the sitting of the 9th of this month, the Academy of Sciences has heard a communication from M. Grimand, relating to a substance which he names *lactoline*, which, mixed with nine-tenths [nine times its quantity?] of water, reproduces fresh milk. The substance is not injured by moisture or heat.

NEW DISEASE OF HOGS.

To the Editor of the Farmers' Register.

Cambridge, Md., May 16, 1835.

* * * * To fill up my sheet, allow me to make an inquiry through your widely circulating and invaluable journal, whether a certain disease lately appearing among my hogs, and here quite original and fatal, has been known elsewhere, and a remedy discovered for it. I had last fall twenty-seven shotes, of a very large and valuable breed—six months old—running on clover, and penned and fed every night and morning with corn. In September, one was attacked with a cough, and shortly after a large majority of them. I then separated the diseased from the healthy—the progress of the disease was not rapid, but very fatal—in four or five weeks the animal continuing fat, and with good appetite during that period, began to decline; the cough became violent and convulsive, assuming the appearance of a most inveterate "pertussis." When seized with a paroxysm, the animal would stand contracted in violent agony, coughing for several minutes; its sides spasmodically working, as if it would not survive it. In six or eight weeks from the commencement, a diarrhœa with malignant odor of the whole animal, supervened, and death ensued. I lost nine of these shotes with this disease. In March last, every farrow of the sows remaining on that farm where the disease had appeared, suffered under the same symptoms, and many pigs have died with it. The pigs of several sows removed, previous to farrowing, to a distant farm, were wholly exempt—and what is very mysterious, having sent off the diseased pigs, and brought home to the first farm those sent to the distant one, they began a few days ago to manifest symptoms of the same disease. Therefore, the disease is not only very malignant, but obviously contagious in the highest degree—the yard having been well cleansed before they were introduced.

From the Richmond Compiler.

IMPORTED SHEEP AND HOGS.

Mr. Corbin Warwick, whose farm on James River is stocked with some of the finest animals in the state, has lately imported, from the stock of Mr. Coke, of Holkham, the celebrated English farmer, several sheep of the southdown breed, and two hogs of an extraordinary size. These pigs (which pass pretty well for "whole hogs,") are but nine months old, and yet we should estimate the weight of each at about 400 lbs.

Those who feel an interest in an examination of superior stock, can see these astonishing animals at the lot of Mr. Warwick, adjoining his new residence.

From the Genesee Farmer.

TIME FOR PAINTING HOUSES.

Repeated experiments show that paint put on houses late in autumn, or in winter, will last far longer than that put on in warm weather. In cold weather the oil dries on the clapboards, and with other ingredients forms a durable body, but in hot weather the boards absorb the oil, and what remains on the surface has but little substance.

DELINQUENT SUBSCRIBERS.

Before issuing this 2nd No. of Vol. III, we have erased from our list *nearly* all the names of those subscribers who have received the Farmers' Register from the commencement of vol. I, and have made no payment whatever. If among these there should be included the names of some whose payments have remained due merely from inattention, the erasure will be cause for regret, but is a consequence which the publisher cannot possibly avoid.

This measure will make a heavy *nominal* reduction of the list of supporters of the Farmers' Register—but will be in truth a considerable addition to the clear profit of the publication. Heretofore this journal has been sent to every person who wrote for it, and even to those in the most remote parts of the United States, though totally unknown, and when the orders for the work were accompanied by neither money nor available references. Under such circumstances, (justifiable only by the necessity of extending the circulation of a new work,) it might be expected that there would be very many bad debts. But this extent of confidence has not been often abused: and, taken altogether, the payments have been made with a rare degree of punctuality—and if every subscription now erased remains in default, the proportion of payments made will still be unusually large. It is hoped and believed that the present reduction of numbers will leave a still more sure and solid support to the work.

TERMS OF PUBLICATION FOR FARMERS' REGISTER

1. The Farmers' Register is published in monthly numbers, of 64 large octavo pages each, and neatly covered, at $5 a year—payable in advance.

2. Or five *new* subscribers by sending their names and $20 at one time to the editor, will receive their copies for one year, for that sum, or at $4 for each. Purchasers of any 5 volumes (except Vol. I.) at one time in like manner, shall have them for $20.

3. The risk of loss of payments for subscriptions, which have been properly committed to the mail, or to the hands of a postmaster, is assumed by the editor.

4. For all copies not received by mail, duplicates will be furnished to those subscribers who have complied with their own obligations.

5. If a subscription is not directed to be discontinued before the first number of the next volume has been published, it will be taken as a continuance for another year.

6. The mutual obligations of the publisher and subscriber, for the year, are fully incurred as soon as the first number of the volume is issued: and after that time, no discontinuance of a subscription will be permitted. Nor will a subscription be discontinued for any earlier notice, while any thing thereon remains due, unless at the option of the editor.

AGENCY FOR THE FARMERS' REGISTER.

James Anderson, Esq. (now of Richmond) is appointed agent for the Farmers' Register, and is authorized to receive the names and payments of new subscribers. With this object, Mr. Anderson will soon commence a tour through Virginia, commencing with some of the upper counties.

This agency will in no way affect any other previous arrangements, nor the directions for transmitting other names and payments stated in the terms of publication.

NOTE TO PROF. DEW'S ESSAY ON PRICE.*

The price of lands in Virginia will be kept down in some measure, by the disproportionate rise in the price of negroes, for this reason. Land and negroes make up the capital of the farmer; and the produce which he sells after deducting the expense of cultivation, constitute his net revenue, or profits. Now supposing the value of negroes to increase very rapidly, it is evident that the amount of the farmer's capital will increase in the same proportion, provided the value of the land does not change. That being the case, if his productions remain stationary, or do not increase proportionally in price, it is evident there will be a fall in agricultural profits. Thus suppose there be a farm with 40 negroes, valued at $10,000 while the land is valued at the same, making an aggregate capital of $20,000. Suppose the produce after deducting expenses of cultivation, to sell for $2,000, the latter will be the farmer's profits on $20,000, a profit of 10 per cent. Now suppose a sudden rise to take place in negroes, so that the 40 are worth $20,000, then the capital of that farmer swells to $30,000, and if you suppose the price of his *neat produce* ("*produit net*,") to sell for $2,000 only, as before, then his profits will fall to $6\frac{2}{3}$ per cent. The consequence would be that persons with money capital would not buy land and negroes because of this fall in profits, and that would occasion a fall in land, till agricultural profits bore a proper ratio to agricultural capital. Now the present rise in the price of negroes being occasioned more by causes extraneous to Virginia, than by the rise of her own native products, upon the principle just elucidated, this rise in price will rather have a tendency to check any rise which might otherwise take place in lands, and of course to prevent the speculating rage from reaching them to the same extent as in the south-western cotton country, where the price of cotton, and the extension of the credit system to its utmost limits, will most certainly push the mania for land speculation to a most perilous and alarming extent, soon to be checked by one of those disastrous revulsions, which will spread ruin and dismay throughout that country. In the mean time, the whole banking system of the south-west, if not judiciously managed, may be looked upon as the mighty engine of the times, which by its potent agency, will hasten on the crisis, and magnify the calamities of the final catastrophe.

*This was received after the article for which it was designed, had been printed, and therefore the note necessarily stands separately.

THE FARMERS' REGISTER.

VOL. III. JULY, 1835. No. 3.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

ON THE RELATION OF CERTAIN PLANTS TO THE INGREDIENTS OF THE SOIL ON WHICH THEY GROW.

To the Editor of the Farmers' Register.

Your statement in a late number (12) of the Register, has satisfied me that the white or mountain locust (*Robinia pseudacacia,*) is native on the calcareous banks of the lower James River, and perhaps on similar soils of other streams emptying into the Chesapeake.

This brings to mind some similar facts which I had before noted. Bartram, in his Travels through the Southern States, long ago published, remarked, with surprise, the leather-wood (*Dirca palustris,*) and some other northern plants growing on *calcareous hills* in the lower part of Georgia. With equal surprise I remarked the same plant (*Dirca palustris,*) the calycanthus floridas, and a yew tree, (*Taxus montana*?) growing on calcareous knolls in Florida. Pursh found *taxus canadensis* on the banks of one of the streams in Maryland, probably on similar soil.

From these facts may we not conclude that calcareous soils have considerable effect in protecting growing plants from the injurious influence of an ardent sun and a warm climate? And from this may possibly be derived a hint of some value to the agriculture of the south. Thus, is it not probable that, on calcareous soils, good crops of wheat might be obtained in those parts of the southern states where it does not thrive well in the ordinary soils?

It is said that wheat does well in the prairies of Alabama, and I think you have remarked that the growth of clover is much promoted by marling in lower Virginia.

How is it that these soils have this effect? Is it simply by their tendency to *retain* the moisture afforded by rains and dews?

H. B. C.

Newbern, N. C., May 20th, 1835.

P. S. You may be assured that the honey locust is a native of the southern states, and I believe of the northern also.

[Our correspondent is on the right track of an interesting pursuit, which promises abundant and important results to the investigator who is aided by botanical knowledge, and by the wide range of observation afforded by travel. It is gratifying that the subject has now engaged the attention of one who may throw much light on it, and the few facts and deductions to which our correspondent refers, may lead him to others far more interesting. Even under all the acknowledged deficiencies of means for this investigation, we have long ago learned that the limits of the localities of various plants which were supposed to be regulated by climate, were in truth determined solely by the ingredients of the soil; and of all differences in soils in this and other respects, the greatest by far, the most important, and yet the least noticed heretofore both by cultivators and scientific men, is the difference caused by the presence or absence of calcareous matter. We earnestly hope that at least some curiosity is now excited on this subject, and that it will be properly investigated by those who have ample powers and means for the purpose.

The power which calcareous earth gives to soil (directly or indirectly) of attracting and retaining moisture, is an important aid to clover and other plants which require it. But this is far from being its only, or its greatest agency. Many plants, and clover is one of them, require lime as part of their food, without which they can scarcely exist, and certainly cannot thrive, even with every other requisite for growth. Except on a few favored soils, profitable clover culture was impracticable in all lower Virginia before the use of marl, or lime—and since marling, (and with other aids,) growths as luxuriant, as hardy, and as profitable, have been produced in our neighborhood, as any in the rich limestone lands of Pennsylvana; and this on soils that were formerly very poor, and naturally as unfavorable as any to this grass. Still these instances are rare, because the improvement has not yet been extended far, and because all that has yet been written and done, has not removed the long established and general, though erroneous impression, that our hot summers and sandy soils prevented the success of clover. Even our very intelligent correspondent, when alluding to the truth which we are desirous of having inculcated, does not appear to attach to it any thing like its due importance.

It would seem, from chemical observations, that the phosphate of lime is an essential ingredient of wheat —and therefore, that without a sufficiency of that ingredient in the soil, that grain cannot be produced. Whenever there is enough lime in the soil, in any form, wheat will be sure to obtain this necessary but small proportion of the phosphate. But in many extensive regions, as in New England generally, (on uplands,) it is said that wheat cannot be profitably raised —and doubtless, on account of the deficiency of lime in the soil. A quantity of lime too small to cause much improvement of soil, might serve to supply this essential food for wheat—and even a still less quantity of bone manure, the solid part of which consists entirely of phosphate of lime. But such facts are more strikingly manifested by certain plants, which thrive in plenty either upon the total absence, or abundance, of calcareous matter, and which cannot be found under opposite circumstances—as the mountain locust and papaw which we before cited, and others named above—and sheep sorrel, and our poverty grass, (or "hen's nest grass" as commonly called,) both of which are the most abundant growths of our poor soils destitute of lime, and of which not a trace will be found as soon as the land has been made calcareous. The observation of these and similar facts would often serve to indicate the nature, and degree of permanent value of soils, even to the rapid glance of a traveller.

It is to invite such observations that we have offered this hasty comment on our correspondent's remarks. It is astonishing what little attention the writers of descriptive travels (and even those who exhibit their knowledge of geology, mineralogy, chemistry, and botany,) have given to the composition of the soils of the regions which they described. Except from some incidental observations, or minor facts, it is rare that their readers can learn any thing, even indirectly, on this important subject.

But it is time to close these remarks, which are already too extended for their place, and yet too slight for the subject.

CALCAREOUS SOILS NECESSARY FOR VINEYARDS.

In some former remarks introductory to extracts from Bushby's *Journal of a recent visit to the principal Vineyards of Spain and France*, we offered the opinion that calcareous soil was essential to the perfection of grapes, and for obtaining from them wines of the finest flavor; and that to the want of calcareous matter in all the soils used for that purpose in the United States, was probably owing, in part at least, the general ill success of our culture of the vine. The opinion of the superior fitness of calcareous soils for vines, was partly founded on a short passage of the work above named, which described the soil that produces the celebrated Hermitage wine, as being highly calcareous. For that, and other extracts then given, we were indebted to a review of the *Journal*, (never having seen the entire work)—and in another review, just now met with, we find the following extract from the same work, presenting a statement of facts on this head, and more direct and full proof of the truth of the opinion which we before advanced.

When the author speaks of "calcareous soils" it may be inferred from the context (here and in the extract formerly published,) that he means *highly* calcareous—either actual chalk soils, or otherwise such as effervesce freely with acids. But it may be presumed that many if not all the other soils, which he speaks of as not calcareous, though producing good "sweet wines," have lime in some form. He does not seem to speak with much precision on this point—and the soils which he considers not calcareous, may contain more lime than any vineyards in the United States. But without this supposition, it is stated expressly that two-thirds of all the vineyards of France are on calcareous soils, and all those of both France and Spain "producing dry wines of reputation." Is not this statement (putting aside all theory and supposition,) enough to induce the making the soil of some vineyard in this country calcareous? There is scarcely an acre of soil, naturally calcareous, in any of the Atlantic states, and probably not one vineyard, if even one vine, has yet the benefit of a heavy cover of calcareous manure. Yet, from the small space occupied by a vineyard, and the great value of the products, marl or lime might be profitably used at an expense very far exceeding what would be justified by any other crops. If our view is well founded, if it cost $100 to make an acre of vineyard calcareous, it would be a profitable expenditure, compared to the culture, for a number of years, with the usual degree of success. Being a permanent improvement, the cost would be only equal to the interest of the outlay, or six dollars a year—which an improvement of quality of the wine of only a cent in the gallon would greatly overpay. We earnestly recommend the consideration of this matter to several of our subscribers near Richmond and Petersburg who have vineyards, and who could, at very little expense, make the trial. But enough of mere opinion. We proceed to give the author's facts as well as his opinions, in his own words.

"Having recorded with so much minuteness my observations on every vineyard and district through which I passed, I will avoid adding to the length of this journal by offering many general remarks. I cannot, however, refrain from observing, that, from the albarizas of Xeres, the most southern vineyards of any reputation in Europe, to those of the chalky hills of Champagne, amongst the most northern, I met with no vineyard producing dry wines of reputation which was not more or less calcareous. Although it is acknowledged that two-thirds of the vineyards of France are situated upon soil more or less calcareous, by Chaptal, and other writers upon the subject, they have stated that, provided the soil is porous, free, and light, its component parts are of little consequence; and they enumerate granitic, schistose, argillaceous, flinty, sandy, and calcareous soils as equally well qualified to produce, and as actually producing, in different parts of France, wines of the finest quality. It appears evident to me, however, that these writers have, in many instances, been misled by the representations which have been transmitted to them: as, for instance, when Chaptal and Cavoleau cite the wine of Hermitage as an instance of the excellence of wines produced upon the debris of granite; while the fact is, that the wine of the hill of Hermitage owes its superiority over the wines of the other hills in its neighborhood only to the circumstance of the granitic soil of a part of that hill being mixed with calcareous matter; and, but for this circumstance, I am satisfied that the wine of Hermitage would never have been heard of beyond the neighborhood where it grows. I am therefore of opinion, that the finest dry wines owe their superiority chiefly to the quality of the soil; and I am much mistaken if it be not found that the soils of all vineyards producing dry wines of superior excellence are strongly calcareous. All my observations have led me to this conclusion, and I know of no instance to the contrary. It will be observed, that I here only speak of dry wines, for sweet wines of great excellence are produced in a variety of soils, and in fact, owe their qualities more to the variety of the grape, and the manner in which it is treated, than to the soil. The sweet *Muscat* and *Old Mountain* wines of Malaga are celebrated all over the world; but though they have the same varieties of vines at Malaga as at Xeres de la Frontera, and pursue a similar practice in making the wine, the best of their dry wines, produced on a soil consisting of decomposed slaty schist, are insipid and flavorless when compared with the Sherries which are produced on the chalky hills of Xeres. The sweet wine of Rivesaltes, the most celebrated in France, is produced on a granitic soil covered with pebbles; and the sweet wines of Cosperon and Collioure, in the same department, are produced on hills of schist, as nearly as possible resembling those of Malaga. But though the dry wines of both these soils are well known, they are not distinguished for their fineness or flavor. Their excellencies are their strength and rich color, which make them valuable for mixing with the weak and light colored wines of the ordinary growths of Burgundy and Maçon which supply the chief consumption of Paris.

"The limited extent of the first-rate vineyards is proverbial, and writers upon the subject have almost universally concluded that it is in vain to attempt accounting for the amazing differences which are frequently observed in the produce of vineyards similar in soil and in every other respect, and separated from each other only by a fence or a foot-path. My own observations have led me to believe that there is more of quackery than of truth in this In all those districts which produce wines of high reputation, some few individuals have seen the advantage of selecting a particular variety of grape, and of managing its culture so as to bring it to the highest state of perfection of which it is capable. The same care has been extended to the making and subsequent management of their wine, by seizing the most favorable moment for the vintage—by the rapidity with which the grapes are gathered and pressed, so that the whole contents of each vat may be exactly in the same state, and a simultaneous and equal fermentation be secured throughout—by exercising equal discrimination and care in the time and manner of drawing off the wine, and in its subsequent treatment in the vats or casks where it is kept—and, lastly, by not selling the wine till it should have acquired all the perfection which it could acquire from age, and by selling, as the produce of their own vineyards, only such vintages as were calculated to acquire or maintain its celebrity. By these means have the vineyards of a few individuals acquired a reputation which has enabled the proprietors to command almost their own prices for their wines; and it was evidently the interest of such persons that the excellence of their wines should be imputed to a peculiarity in the soil, rather than to a system of management which others might imitate. It is evident however, that for all this a command of capital is required, which is not often found among proprietors of vineyards; and to this cause, more than to any other it is undoubtedly to be traced, that a few celebrated proprietors have acquired, and maintained, almost a monopoly in the production of fine wines."

EXTRACTS FROM A REPORT ON SELECT FARMS,

Made by an examining committee, appointed by the Société d'Agriculture et d'Economie Domestique de Rosay (Seine-et-Marne.) September, 1834.

Translated for the Farmers' Register, from the *Annales de l'Agriculture Francaise*, of November, 1834.

[Of the farm of Chapelles, only part of the observations of the committee are here given, and that, principally, because of the more full notice of the four-shift rotation, which is again referred to in the succeeding statements. Of the two farms of Noas and La Grange, to which the two first prizes of the society were awarded, the remarks of the committee are given entire. The reports on six other farms are omitted. Whether the details here presented to our readers may possess any practical agricultural value, or not, those relating to La Grange will be of some interest, as exhibiting something of the private life, and humble but useful labors, of the illustrious man who belonged to our country as much as to that which gave him birth, and to the world—and whose deeds were more for mankind, and less for self aggrandizement, than those of any, or all the *great men* now leading or governing nations, or striving to attain such eminence.]

Farm of Chapelles, belonging to M. Caron, cultivated by M. Vignier.

The tillage of the lands belonging to the farm of Chapelles, is almost completely subjected to the four-shift rotation, based upon the sowing of clovers on wheat, and of oats upon the clover lay—the rotation most suitable for all kinds of land, because it is readily accommodated to all the partial modifications which may be suggested by the circumstances of the farmer, and of his land—and which is inflexible only on one point, viz: the constant alternation of grain crops and artificial grasses.

M. Vignier did so much the better in adopting this improvement, as his land, naturally wet, having been put in lucerne by a preceding tenant, could no more bear that grass, notwithstanding all his care to establish it. He has not succeeded in making it grow, except upon a lot of land which had not yet borne it. He attributes his success to the use of *poudrette*,* of which he has sown a great quantity at the same time with the lucerne seed. The growth on the part thus sown, is much finer than that of the same ground, in lucerne without *poudrette*. M. Vignier makes considerable use of this manure, of which he knows the good effects on wheat. It is said that its effect is not prolonged beyond that of one crop: but he has made an observation on that head, which deserves to be cited. This is, that a crop of clover, made upon wheat manured from the farm-yard, where there had been, four years before, wheat made on *poudrette*, grew much finer than the other clover made after two such crops of wheat on farm-yard dung, or one crop manured by penning, and one from the farm-yard. Perhaps we ought to conclude that this alternation of *poudrette* and farm-yard manure suits best, especially for humid soils, because that the *poudrette*, by its effervescent action making the soil enter into fermentation, acts not only as [alimentary] manure, but as an improver of the texture of the soil. After the wheat, without doubt the part serving as manure is exhausted, as the action of the *poudrette* is very quick: but the improvement of the soil remains—the earth is warmed, reanimated, and more proper than any other to bear good crops, with the addition of farm-yard manure.

The rotation of the farm of Chapelles is certainly that which suits it the best, and M. Vignier follows it with perseverance and intelligence. All his ploughings are well executed, his ground in the best state of preparation—and yet, though the land of this farm may be of good enough quality, the products are not such as would be desired. The crops of this year, especially, are far from answering to a culture so judicious and well executed. The wet nature of the soil is opposed to complete success: it requires to be tilled precisely at such times and seasons as it is in the best order for receiving tillage, and without permitting the commencement of the difficulties by which the crops suffer. The amelioration of the soil is not yet enough advanced—there remain

*This is dried and pulverized human excrement—prepared generally in towns in France, where large quantities of the material can be collected from privies, or from cleaning out the public "*fosses des aisance.*" —Tr.

still too many traces of imperfect culture—the lands are disposed to get foul with weeds very quickly. These various reasons oppose the suppression of naked fallows, (which he cannot use but with much caution,) and of course, oppose the developement of a system of agriculture entirely prosperous. * * * *

M. Vignier has attempted this year to make a large quantity of field beets, [*betteraves*] or mangel wortzel, (seventeen arpents;)* they were not advanced at the time of our visit, but were coming on well, and will doubtless give good products. He regularly has ten arpents in potatoes, well cultivated.

We remarked a field of rape [*colza*] of some arpents, promising a good crop. This is a novelty, which is so much the more useful as it has had complete success, which will, without doubt, encourage the cultivators of the country to follow the example.

The proprietor of this farm, M. Caron, has not confined to the buildings his participation in the improvements. He has devoted himself, with interest, to all that can favor the culture of the land. A general marling—numerous ditches which he has made at the demand of the farmer—plantations of fruit trees—roads—in short, all that can be useful, is executed by him as soon as the utility is known.

* * * * * *

Farm of Noas—Commune de Pécy.

It is on the farm of Noas that we have seen established most completely, and with the most remarkable success, the regular four-shift [*quadriennal*] rotation. On a middling soil, there are seen the finest crops. Upon 400 arpents of arable land, nearly all unfit for lucerne, M. Vignier cultivates 100 arpents of wheat—70 in clover, made on the manured wheat—90 in oats, of which 70 are upon a clover lay, [*defriche des trefles*,] the balance upon a lay of lucerne, or after vetches, or potatoes, or other roots.

We will again call attention to this point, that generally the soils of this farm are middling—in many places even the land is very bad. Well! no where is there found a bad crop: every part bears what might be hoped from good culture, with success proportioned to the worth of the different pieces of land compared with each other.

The fallow (this year lost for the bad cultivator) is in this farm devoted entirely, according to a rational system, to the melioration of the land, and to the production of useful crops. Fifteen arpents only have been left in naked fallow: this was the part which had need of repeated ploughings, perfectly executed, and at precise times, to bring it to the state of good order common to the other land of the farm: the remainder had been in rye, grazed by the sheep, and in vetches, also grazed or cut green; and five arpents in potatoes and thirty-five in field beets or mangel wortzel. These roots are made after three ploughings, and receive three hoeings [*binages;*] they are of the finest growth, and promise a very abundant crop. M. Vignier has told us that he has made this root at the rate of about 35,000 weight to the arpent—which may perhaps be equivalent to 1000 *bottes* of dry forage. He prefers the beet to the potato, for the consumption of beasts, because it appears to him to contain less of the water of vegetation—and also for the preparation of the soil, because that wheat grows well enough after the beets, whilst the trials that he has made after potatoes have been without success.

The interior of the farm, [homestead, or farm buildings] answer well to the exterior culture. A cow-house contained 24 cows of the finest form, in the best condition, and appearing fit to yield good products. The flock consisted of about 700 sheep, and 200 lambs, all of fine wool. The grown sheep are in good condition; but the lambs appeared not to be in such state as might have been expected. It appeared that the pasturage being short, the lambs had not yet been turned out. This is the only thing which the inspection of this fine establishment showed to be defective; but the good state of the rest of the flock, proves that circumstance is but accidental: and it should be remarked, that the range or "commons" [*parcours*] of the farm is limited to about 450 arpents, near the lands which compose it.*

M. Vignier has established at Noas, at his own expense, those parts of buildings which would have been deficient, as extensive sheds, sheep folds of light construction, and a thrashing machine.

We have no need of telling you, gentlemen, how much satisfaction we have experienced in visiting the establishment of M. Vignier. Such complete success of intelligent labor has confirmed us in the opinion, that the most prosperous destiny awaits agriculture, when it shall have received the developements of industry.

* * * * * *

Farm of La Grange-Blesneau—Commune de Courpalais—belonging to Gen. Lafayette, directed by M. Lécuyer.

We have ended our rural visits with the farm of

---

*The arpent is not now a legal measure in France, and was not uniform every where when it was legal. It does not vary much from our acre.—Tr.

*The "*parcours*" does not consist of pasture land belonging to a particular farm—but to the whole *commune*, or territorial district—and indeed the *parcours* of adjacent *communes*, by law, owe reciprocal service, by which the beasts of one *commune*, may be driven to graze on the territory of a neighboring *commune*. See "*Parcours*" Vol. VII. p. 235, *Cours Complet d'Agriculture etc. par l'Abbé Rozier*. Thus the grass furnished to the flock of any one proprietor, by 450 arpents of "*parcours*," is a very indefinite amount—but could scarcely be of much value in any case. There is another legal right of grazing in France, sometimes (as Rozier says) confounded with this, and which is still more injurious to agriculture. This is the local usage and right of "*vaine pasture*," by which the owners of beasts may graze them upon the lands of the *commune* generally, after the crops have been taken off. A similar usage was getting established in Virginia—and though without legal sanction, would have became "time honored" and irrevocable, if *Arator* had not taught us the necessity of protecting our fields from grazing, and thus induced the expulsion of the intruders, before they had become too strong to be resisted.—Ed. Farm. Reg.

La Grange, which will be celebrated as the place of residence of Gen. Lafayette, and which is also for us an object of particular interest, as a rural establishment founded by that illustrious man, under whose presidency our society was formed.

Around a vast yard, (or court) are arranged the buildings belonging properly to the farm.

There are seen sheep folds large enough for a flock of a thousand head. They are well lighted and ventilated, boarded or ceiled, and once a year whitened with lime; so that the flock is kept in the best condition for health.

The flock is not more than seven to eight hundred head. It was found proper to reduce it on account of the barrenness of the common range, [parcours] of which the product has been lessened by the growth of the trees planted on the borders. The flock which is now in very good condition, has been brought to a high state of improvement by successive crossings of the merinos of Rambouillet, which had formed its primitive foundation with sheep of Saxony, of Naz, and of the flock of M. de Jessaint. Its products have been the object of distinction to the meeting of the department.

The great cow-house can contain about twenty-four cows, and is in the most simple form; only the paved floor of it is so inclined that the urine is collected and preserved in a pit, dug outside of the building, from which it was drawn for use.

The cows are generally fine. Part of them came from Switzerland, and others are the issue of the same race. They are all capable of yielding good products. We name especially the cows of Schwitz, which are the best milkers of the farm, and which M. Lécuyer, its superintendent, places above all known of the best in the country as beasts of profit. The bull is of the same stock.

A second cow-house contains cows of different breeds, particularly an English breed, the Devonshire, of which, but a short time before his death, the General received a bull and two cows from England. These beasts have not yet had time and opportunity to furnish means to appreciate their qualities.

At the end of this cow-house is the stable.

Opposite the window of the proprietor, is the habitation of the superintendent, disposed with simplicity and convenience. At the side is the bake-house, an apartment well occupied in an establishment so extensive, and in which the inhabitants, the masters as well as the laborers, and domestics, eat the same kind of bread. In the bake-house, are the entries of two dairies perfectly well situated and arranged, the one for winter, and the other for summer—and also the entrance of the steaming apparatus, of which we shall speak hereafter.

This apartment, and all connected with it, are kept with a degree of order and neatness, which leave nothing to be desired.

The bread is prepared by using a kneading machine, with the operation of which the superintendent is well satisfied, because the dough is well worked, with less trouble and expense than if kneaded by hand. It is a useful instrument—and indispensable in a house where they bake frequently, and in great quantity.

At the end of this building is the place occupied by a steaming apparatus, which has no other ordinary use except the cooking of an immense quantity of potatoes for feeding all the beasts. At the right and left of the boiler, are two vessels which can contain each, fourteen *setiers* of potatoes, and which, well covered, can be cooked in a few hours, the fire being fed by wood of very little value.

We cannot propose this boiling establishment as a model for imitation, except for a large farm and extensive operations, directed on account of the proprietor, or for a model farm: but there, where it is, it renders great service, and is considered as one of the most useful things. It has been made sometimes to serve for purposes of another kind, which in this house are not less precious: it is to give vapor baths gratuitously to the poor and sick, who could not otherwise procure them.

Gen. Lafayette had recently caused to be made in the farm-yard,* a pit, with two large ditches or drains under the dung hill, to collect the water: above the pit is a pump for the purpose of watering the manure from the pit, and ditches which empty into it.

We noticed the poultry houses which are closed on the south with a grating of iron, which permits free entrance to the air. In another yard, to the north, and serving as entrance to the farm buildings, is the piggery: to this the yard is exclusively appropriated. The greatest cleanliness is here preserved—and the animals find all the attention and space necessary for them. They appear to live well, and to be well managed for the yielding of manure.

Next is the press house, where the wine and cider flow by subterraneous pipes into the cisterns and casks placed in a large vault on one side. On the other side are sheds for the various ploughing utensils: and under these sheds there are immense vaults or cellars under ground, designed to hold the root crops, which are poured down through trap-doors, opening under the sheds.

At the east of these buildings there is yet another yard, where stands a vast granary, closed with frames of planks, which are raised or lowered at will. In this building is fixed a thrashing machine.

A great number of utensils of various kinds are put away under the sheds, and particularly ploughs of all kinds: the plough without wheels of Roville, that of M. Rosé, and others Belgian and American, and the Grangé plough: but all the work of the farm is done with the ploughs of Brie.

The object of M. Lafayette being to obtain immediate returns, new experiments have not been treated by him but as subsidiary, and on a small scale. This is a model farm in respect to the product obtained by a good combination of culture, rather than a theoretical school of agriculture.

The lands of the farm consist of about 500 arpents, of which 100 arpents are in turf and meadows, given almost entirely for pasturage for the sheep.

The remaining 400 arpents are of arable land, divided into fields of 24 arpents, by alleys and rows of apple and pear trees. Of these, 96 arpents are in lucerne, 96 in wheat, 48 in oats, 24 in barley, for the purpose of being sowed in lucerne, 24 ar-

*"*Cour de la ferme,*" the open space surrounded by the farm buildings, and not simply the dung yard, or winter cow-pen, as the term is used here.—TR.

pents in field beets and potatoes, and 96 arpents, instead of being in naked fallow, are entirely laid down in common clover, of which only one cutting is taken, and in crimson clover, [*trefle incarnat*,] rye, vetches and peas, grazed or cut green for feeding cattle.

To the potatoes and beets cultivated on 24 arpents succeed oats, on which common clover is sown. After the first mowing of this clover, this piece returns under fallow. The crimson clover is sown upon the stubble of the wheat or oats, and after being once mowed, it also returns under fallow, with the advantage that, this crop being very forward, the land is ploughed in the same time as if the fallow had been naked.

The rye and the vetches of winter and spring, are made upon the stubbles of wheat and oats, and even a sowing of vetches is again made partially after the grazing of the green rye; and after their being grazed or mowed, these lands are also thrown into fallow, which, as may be seen, follows every year, upon 24 arpents which had borne wheat the preceding year: that is to say, this portion of land is cultivated as if in two-shifts; but only one time, until its turn comes again, which depends on the quantity of land to which this exhausting culture may have been applied.

The numerous flocks of the farm secure the means of suitably manuring from the farm-yard, or by folding, the land designed for the wheat crop. But as one part, which had produced wheat the preceding year, exacts a greater abundance of manure, and as there are 24 arpents of beets and potatoes, which require a great quantity of the better manure, the superintendent of the farm, M. Lécuyer, has sought to multiply his supplies of manure, by composing it of *poudrette* and *urate** with the cleanings of moveable privies, and the urine of the cattle, collected, as before stated, in a covered pit. He showed us the experiments which he has made with this manure this year, on some furrows, compared with manuring by penning, and from the farm-yard: and the wheat on this manure, applied at the rate of ten to twelve hectolitres the arpent, was as good as on the land folded on, or manured from the farm-yard. This manure is made, in part, of matters which ordinarily remain in the farm-yard manure; there is this advantage however, that being destined for a particular use, these matters, which are the excrement of horses and urine of cows, are collected and used with more particular care. We have not seen that the manure in the yard of this farm was inferior to that of other farms. In short, if this supply of manure is not entirely a new product, it is certainly an improvement.

There are on this property many thousand fruit trees, now in full bearing. They have already yielded near 300 casks [*pièces*] of cider; and it is believed that this year, that number will be doubled. The average may be counted at 150 casks a year.

A quantity of forest trees are planted, especially wherever there is a waste spot, however small it may be.

Further—the farm of La Grange, a useful model in many respects, is subjected also to very good and careful tillage. The 24 arpents of roots, the 100 arpents of lucerne, the meadows and pastures, the 100 arpents of clover, rye and vetches, which occupy the fallow, the whole pastured or mowed, give an immense product of forage, so that every year there are sold from the farm ten to twelve hundred *bottes;* which is an important profit, and which has been so for some years.

The root crops, followed by oats, and then by clover, offer a partial rotation well arranged: but what appears to us a fault, is the necessity of taking again for wheat one-fourth of the land which had borne wheat the preceding year, and, to make barley, 24 arpents of the land which had borne wheat. This is to return to a bad system, after having come out of it happily. Wheat made upon common clover may often succeed well; but the success of it in our country, is not enough assured to make it the foundation of a rotation. We do not conceal that we found the land, otherwise well ploughed and manured, giving evidence of the defects of this rotation; and that called, each part in its turn, to undergo this forced production, some are found not in that state of cleanness and fertility, which insures good crops. The lucerne also, made in too large proportion, yields less abundantly: it is to this disproportion that we believe ought to be attributed the defects of this rotation. The four-shift rotation founded upon the sowing of clover on the grain crops, with a less quantity of lucerne, might furnish as much forage for consumption and for sale, and not imposing on the land the bearing of forced products, would maintain it in a better state of fertility. The comparison, while we acknowledge the merit of the good culture of La Grange, has confirmed us in our opinion that the four-shift rotation, such as is followed on the farm of Noas, is the most rational, and the most conformed to the invariable principles of good culture. * * * *

From the Cultivator.

AGRICULTURAL BOOKS.

We have been requested, by a correspondent of the Genesee Farmer, to furnish a list of agricultural books, suitable for a farmer's library. This we do cheerfully, remarking by the way, that the number of *American* books is very limited; and that in selecting those of foreign origin, we must take much chaff with the wheat. The elementary principles of husbandry are pretty general in their application, while the practical operations of different countries must necessarily be variant, not only on account of difference in climate and soil, but in productions for the market, price of labor, habits of the people, &c. No European system of practice is therefore exactly adapted to our wants, though it may embrace much that is highly beneficial.

Independent of the memoirs which have been published by the agricultural societies in Pennsylvania and Massachusetts, and by the Society of Arts and Board of Agriculture in New York, the *American* works on agriculture, that we have been acquainted with, are, to name them in the order in which they appeared, 1. Deon's New England Farmer; 2. Boardley's Husbandry; 3. Arator, a series of agricultural essays, by John Taylor, of Virginia; 4. A Treatise on Agriculture, by Gen.

---

*Urate, in chemical nomenclature, means salt formed by the combination of the uric acid with any base. But as used here, it must be intended for urine collected in, or absorbed by, any other matter whatever.—TR.

Armstrong; 5. The Farmer's Assistant, by John Nicholson; 6. Lorrain's Husbandry; 7. Essay on Calcareous Manures, by E. Ruffin; and 8. The Complete Farmer, by T. G. Fessenden. These are all worthy a place in a farmer's library, as well as the memoirs first named. Of Nos. 1 and 7, new revised editions have lately been published at Boston and Richmond. Of the others, copies are scarce, and the memoirs, we believe, cannot be purchased. No. 4 is a work of merit, comprising a great mass of interesting matter, detailed with great conciseness and perspicuity. No. 6 was written by an excellent practical farmer, who blended a great deal of useful reading and nice observation with an extensive practice. The writer was a self-taught philosopher, who scrutinized narrowly into cause and effect, and we believe was a very successful farmer. The Essay on Calcareous Manures, is an invaluable treasure to all who can avail themselves of lime and marl, as sources of fertility. No. 8 is principally a judicious compilation from the agricultural papers of our country. A new edition is now in the press. There are several American publications which treat of the orchard and the garden, which it is unnecessary to enumerate, as they may be found in all our seed shops.

Of foreign publications upon husbandry, we should recommend the following, in the order we name them:—Low's Elements of Practical Agriculture; Lawrence on Cattle; Davy's Agricultural Chemistry; Sinclair's Code of Agriculture, and, (last, *only* on account of its expense,) Loudon's Encyclopædia of Agriculture. The Farmers' Series, published by the British Society for diffusing useful knowledge, affords an excellent compendium of British husbandry, though but partially adapted to our country.

But neither foreign nor American books ought to supersede the agricultural periodicals of the day. These abound in communications from our best farmers, and detail the improvements which are continually developing in rural labor. We venture to say, there is not a farmer in the Union, of common intelligence and enterprize, who is ambitious to improve his condition, and who takes an agricultural periodical, that is not more than remunerated for his subscription, by the useful information which he acquires from it. They are generally printed in a form to be easily preserved, and they ought to be preserved. We subjoin a list of such as are known to us, for the benefit of the readers of the Cultivator:—

Published quarterly.—The New York Quarterly Journal of Agriculture, at New York.

Monthly.—Southern Agriculturist, at Charleston, S. C.; Farmers' Register, at Shellbanks, Va.; New York Farmer, New York: Cultivator, Albany; Tennessee Farmer, Tennessee; Fessenden's Practical Farmer, Boston; Rural Library, a monthly publication of 32 8vo. pages, New York.

Semi-monthly.—Farmer and Mechanic, Cincinnati, Ohio.

Weekly.—Genesee Farmer, at Rochester; New York Farmer, at New York; New England Farmer, at Boston; Maine Farmer, Winthrop, Me.; Yankee Farmer, Cornish, Me.; Ohio Farmer, Columbus, Ohio; Southern Planter, Columbus, Georgia.

Devoted to Horticulture particularly.—The American Gardener's Magazine, by Hovey & Co., and Horticultural Register, by G. E. Barret, both monthly 8vos., published at Boston.

Devoted to Silk Culture.—The Silk Culturist, at Hartford, Conn., and the Silk Worm, at Albany.

To Orchards and the Vine.—Coxe on fruit trees; Thatcher's Orchardist; Prince's Pomological Manual; Kenrick's New American Orchardist, and Prince, Adlum, Loubat and Rafinesque on the Vine.

The Quarterly Journal of Agriculture and New York Farmer are from the same press, as are the New England Farmer and Practical Farmer. The Rural Library is a re-publication of American works on husbandry and gardening.

We can neither give the prices of all the books we have enumerated, nor refer to the bookstores at which they can be had. The periodicals may be obtained, by addressing the editors of the respective works.

From Gibbon's Decline and Fall of the Roman Empire.

ACCOUNT OF THE EARLY USE OF, AND TRADE IN SILK, AMONG THE ROMANS, AND FIRST INTRODUCTION OF THE SILK WORM INTO EUROPE.

I need not explain that *silk* is originally spun from the bowels of a caterpillar, and that it composes the golden tomb from whence a worm emerges in the form of a butterfly. Till the reign of Justinian, the silk worms who fed on the leaves of the white mulberry tree, were confined to China; those of the pine, the oak, and the ash, were common in the forests both of Asia and Europe; but as their education is more difficult, and their produce more uncertain, they were generally neglected, except in the little island of Ceos, near the coast of Attica. A thin gauze was procured from their webs, and this Cean manufacture, the invention of a woman, for female use, was long admired both in the East and at Rome. Whatever suspicions may be raised by the garments of the Medes and Assyrians, Virgil is the most ancient writer, who expressly mentions the soft wool which was combed from the trees of the Seres or Chinese; and this natural error, less marvellous than the truth, was slowly corrected by the knowledge of a valuable insect, the first artificer of the luxury of nations. That rare and elegant luxury was censured in the reign of Tiberius, by the gravest of the Romans; and Pliny, in affected, though forcible language, has condemned the thirst of gain, which explored the last confines of the earth, for the pernicious purpose of exposing to the public eye naked draperies and transparent matrons. A dress which showed the turn of the limbs, and color of the skin, might gratify vanity, or provoke desire; the silks which had been closely woven in China, were sometimes unravelled by the Phœnician women, and the precious materials were multiplied by a looser texture, and the intermixture of linen threads. Two hundred years after the age of Pliny, the use of pure or even mixed silks was confined to the female sex, till the opulent citizens of Rome and the provinces were insensibly familiarized with the example of Elagabalus, the first who, by this effeminate habit, had sullied the dignity of an emperor and a man. Aurelian complained, that a pound of silk was sold at Rome for twelve ounces of gold: but the supply increased with the demand, and the price diminished with the supply. If accident or monopoly sometimes raised the value even above the standard of Aurelian, the manufactures of Tyre and Berytus were sometimes compelled by the operation of the same causes to content themselves with a ninth part of that extravagant rate. A law was thought necessary to discriminate the dress of comedians from that of senators; and of the silk exported from its native country, the far greater part was consumed by the subjects of Justinian. They were still more intimately acquainted with a shellfish of the Mediterranean, surnamed the silkworm of the sea: the fine wool or hair by which the mother-of-pearl affixes itself to the rock, is now manufactured for curiosity rather than use; and a robe obtained from the same singular materials, was the gift of the Roman emperor to the satraps of Armenia.

A valuable merchandize of small bulk is capable of defraying the expense of land carriage; and the caravans traversed the whole latitude of Asia in two hundred and forty-three days, from the Chinese ocean to the sea coast of Syria. Silk was immediately delivered to the Romans by the Persian merchants, who frequented the fairs of Armenia and Nisibis: but this trade, which in the intervals of truce was oppressed by avarice and jealousy, was totally interrupted by the long wars of the rival monarchies. The great king might proudly number Sogdiana, and even *Serica*, among the provinces of his empire; but his real dominion was bounded by the Oxus, and his useful intercourse with the Sogdoites, beyond the river, depended on the pleasure of their conquerors, the white Huns, and the Turks, who successively reigned over that industrious people. Yet the most savage dominion has not extirpated the seeds of agriculture and commerce, in a region which is celebrated as one of the four gardens of Asia; the cities of Samarcand and Bochara are advantageously seated for the exchange of its various productions; and their merchants purchased from the Chinese the raw or manufactured silk which they transported into Persia for the use of the Roman empire. In the vain capital of China, the Sogdian caravans were entertained as the suppliant embassies of tributary kingdoms, and if they returned in safety, the bold adventure was rewarded with exorbitant gain. But the difficult and perilous march from Samarcand to the first town of Shensi, could not be performed in less than sixty, eighty, or one hundred days; as soon as they had passed the Jazartes they entered the desert; and the wandering hordes, unless they are restrained by armies and garrisons, have always considered the citizen and the traveller as the objects of lawful rapine. To escape the Tartar robbers and the tyrants of Persia, the silk caravans explored a more southern road; they traversed the mountains of Thibet, descended the streams of the Ganges or the Indus, and patiently expected, in the ports of Guzerat and Malabar, the annual fleets of the West. But the dangers of the desert were found less intolerable than toil, hunger, and the loss of time; the attempt was seldom renewed, and the only European who has passed that unfrequented way, applauds his own diligence, that in nine months after his departure from Pekin, he reached the mouth of the Indus. The ocean, however, was open to the free communication of mankind. From the great river to the tropic of Cancer, the provinces of China were subdued and civilized by the emperors of the North; they were filled about the time of the Christian æra with cities and men, mulberry trees and their precious inhabitants; and if the Chinese, with the knowledge of the compass, had possessed the genius of the Greeks or Phœnicians, they might have spread their discoveries over the southern hemisphere. I am not qualified to examine, and I am not disposed to believe, their distant voyages to the Persian gulf or the Cape of Good Hope: but their ancestors might equal the labors and success of the present race, and the sphere of their navigation might extend from the isles of Japan to the straits of Malacca, the pillars, if we may apply that name, of an Oriental Hercules. Without losing sight of land, they might sail along the coast to the extreme promontory of Achin, which is annually visited by ten or twelve ships laden with the productions, the manufactures, and even the artificers, of China; the island of Sumatra and the opposite peninsula, are faintly delineated as the regions of gold and silver: and the trading cities, named in the geography of Ptolemy, may indicate, that this wealth was not solely derived from the mines. The direct interval between Sumatra and Ceylon is about three hundred leagues: the Chinese and Indian navigators were conducted by the flight of birds and periodical winds, and the ocean might be securely traversed in square-built ships, which, instead of iron, were sewed together with the strong thread of the cocoa-nut. Ceylon, Serendib, or Taprobana, was divided between two hostile princes; one of whom possessed the mountains, the elephants, and the luminous carbuncle, and the other enjoyed the more solid riches of domestic industry, foreign trade, and the capacious harbor of Trinquemale, which received and dismissed the fleets of the East and West. In this hospitable isle, at an equal distance, (as it was computed) from their respective countries, the silk merchants of China, who had collected in their voyages aloes, cloves, nutmeg, and santal wood, maintained a free and beneficial commerce with the inhabitants of the Persian gulf. The subjects of the great king exalted, without a rival, his power and magnificence; and the Roman, who confounded their vanity by comparing his paltry coin with a gold medal of the emperor Anastosius, had sailed to Ceylon, in an Ethiopian ship, as a simple passenger.

As silk became of indispensable use, the emperor Justinian saw, with concern, that the Persians had occupied by land and sea the monopoly of this important supply, and that the wealth of his subjects was continually drained by a nation of enemies and idolaters. An active government would have restored the trade of Egypt and the navigation of the Red Sea, which had decayed with the prosperity of the empire; and the Roman vessels might have sailed, for the purchase of silk, to the ports of Ceylon, of Malacca, or even of China. Justinian embraced a more humble expedient, and solicited the aid of his Christian allies, the Æthiopians of Abyssinia, who had recently acquired the arts of navigation, the spirit of trade, and the seaport of Adulis, still decorated with the trophies of a Grecian conqueror. Along the African coast, they penetrated to the equator in search of gold, emeralds, and aromatics; but they wisely declined an unequal competition, in which they must be always prevented by the vicinity of the Persians to the markets of India; and the emperor submitted to the disappointment, till his wishes were gratified by an unexpected event. The gospel had been preached to the Indians: a bishop already governed the Christians of St. Thomas on the pepper-coast of Malabar: a church was planted in Ceylon, and the missionaries pursued the footsteps of commerce to the extremities of Asia. Two Persian monks had long resided in China, perhaps in the royal city of Nankin, the seat of a monarch addicted to foreign superstitions, and who actually received an embassy from the isle of Ceylon. Amidst their pious occupations, they viewed with a curious eye the common dress of the Chinese, the manufactures of silk, and the myriads of silkworms, whose education (either on trees or in houses) had once been considered as the labor of queens. They soon discovered that it was impracticable to transport the short lived insect, but that in the eggs a numerous progeny might be preserved and multiplied in a distant climate. Religion or interest had more power over the Persian monks than the love of their country: after a long journey, they arrived at Constantinople, imparted their project to the emperor, and were liberally encouraged by the gifts and promises of Justinian. To the historians of that prince, a campaign at the foot of mount Caucasus has seemed more deserving of a minute relation than the labors of these missionaries of commerce, who again entered China, deceived a jealous people by concealing the eggs of the silk worm in a hollow cane, and returned in triumph with the spoils of the East. Under their direction, the eggs were hatched at the proper season by the artificial heat of dung; the worms were fed with mulberry leaves; they lived and labored in a foreign climate: a sufficient number of butterflies was saved to propagate the race, and trees were planted to supply the nourishment of the rising generations. Experience and reflection corrected the errors of a new attempt, and the Sogdoite ambassadors acknowledged, in the succeeding reign, that the Romans were not inferior to the natives of China in the education of the insects, and the manufactures of silk, in which both China and Constantinople have been surpassed by the industry of modern Europe. I am not insensible of the benefits of elegant luxury; yet I reflect with some pain, that if the importers of silk had introduced the art of printing, already practised by the Chinese, the comedies of Menander and the entire decades of Livy would have been perpetuated in the editions of the sixth century. A larger view of the globe might at least have promoted the improvement of speculative science; but the Christian geography was forcibly extracted from texts of scripture, and the study of nature was the surest symptom of an unbelieving mind. The orthodox faith confined the habitable world to one temperate zone, and represented the earth as an oblong surface, four hundred days journey in length, two hundred in breadth, encompassed by the ocean, and covered by the solid crystal of the firmament.

From the Baltimore American.

REGION OF THE TEA PLANT.

A letter has been received by a gentleman of Philadelphia from the Secretary of the Asiatic Horticultural and Agricultural Society at Calcutta, stating that the tea plant has been discovered growing abundantly in the north-east portion of the British possessions in India, adjoining the province of Yunar in China, in which the plant is cultivated. The discovery is announced as one of great importance. It may be doubted however whether it will prove so. Good teas like good wines only grow in particular districts. A vast quantity of the tea raised in China is so ordinary as to be unfit for exportation, and the plant produces best between the 26th and 30th degree of latitude. By a reference to the map, it will be seen that the north-east region of British India does not extend beyond the twenty-fourth degree of latitude. In China itself, although the culture has been widely extended to meet the increased demand throughout the world, by far the best teas are confined to the two original provinces. The inhabitants of Tonquin and Cochin China, countries lying almost between China and British India, are consumers of tea, but are obliged to go to China for their best, being able to raise nothing but a very coarse black tea on their own territory.

From the New York Farmer.

POTASH AS A MANURE.

I was pleased to see an inquiry suggested in a recent number of the New York Farmer respecting the use of potash as a manure as practised on Long Island, but regret to find no answer furnished by those to whom the inquiry was directed. In the absence of better information on the subject, permit me to state what has been my brief experience in the use of this manure.

I had a lot of meadow land, containing about three acres, which had been reduced to poverty by severe cropping. On this piece of ground I made the following experiment. Having broken up the sward, and harrowed it repeatedly until quite mellow, I spread leeched ashes over one acre, and potash dissolved in water over the other two acres; sowed millet seed, clover, and timothy, all mixed together, in the proportion of one part of each of the latter to five of the former, and one bushel of the mixture to an acre; harrowed all in together on or about the first of sixth month.

The ashes cost fifteen dollars; the potash five dollars the acre; the expense and trouble of dressing with potash, about in the same proportion. And now it was a matter of no small interest to me, a novice at farming, to observe the result of an experiment, which when made, I supposed to be entirely original. The crop of millet was fine, and as nearly alike as could have been expected, if the land had all been covered with the same kind of manure. The clover also, all over the lot, was luxuriant, and gave the strongest evidence, to my mind, that potash is the principal agent in leeched ashes, which causes fertility. I made trial of potash on a lot of four acres, which was considered the poorest on my farm, on which I sowed millet with the potash. I sowed at the same time four other acres without any manure, on ground considered much better than the last above mentioned.

I cut double the quantity of hay from that dressed with potash, and of a better quality. Thus far my little experience goes in favor of potash as a manure; but I much desire that some of thy subscribers, of larger experience, and abler pens, would favor us with light on this interesting subject.

T. D.

Burlington 4th mo. 8th, 1835.

[The foregoing statement shows that potash is, for the first year, as productive a manure as leeched ashes, and at only one-third of the cost. But the writer is greatly mistaken in supposing the fertilizing principles of both to be the same. They may be similar and equal in the effects produced, but are still very different in composition. If the ashes were completely "leeched," they were deprived entirely of that substance of which the other manure consisted entirely. The fertilizing principles of such ashes, consist principally of, first, carbonate of lime, second, phosphate of lime, (far more valuable than the carbonate,) and if obtained from a soap factory, of some quick lime besides, added to aid the separation of the potash. All these last are permanent manures—and the potash being a soluble substance, and applied in small quantities, is probably of transient benefit.—Ed. Farm. Reg.]

William and Mary College, June 3, 1835.

To the Editor of the Farmers' Register.

Dear Sir—Since my article on the fluctuation of price was forwarded to you, the stockholders of the James and Kanawha improvement have met, organized the company of directors, and appointed their president. The directors, I understand, are intelligent, business men, stationed along the whole line of the contemplated improvement, and earnestly devoted to its advancement. The gentleman whom they have chosen president has devoted the last six or seven years of his life almost exclusively to the cause of internal improvement. He has displayed in its behalf ability, untiring zeal, and persevering industry, almost unparalleled. Under these favorable auspices, the great central improvement of Virginia will no doubt be quickly executed—producing an influence on the economical, political, and moral condition of our state almost incalculable.

In the exposition which I have given of prices I have spoken of the deleterious drain of our population and capital to the west, and its effect on the price of real property, and of labor in Virginia. The contemplated improvement in our state is calculated to exercise so salutary and so powerful a counteracting influence in this respect, that I have supposed my article on price would be incomplete without this little *addendum*, explaining briefly my views of the operation of the James and Kanawha improvement on emigration, and on the prices of real property, and labor.

With high respect, &c.

T. R. DEW.

THE IMPROVEMENT OF THE JAMES AND KANAWHA RIVERS—MISCHIEVOUS EFFECTS OF THE EMIGRATION TO THE WEST.

For the last half century Virginia has been pouring forth upon the regions of the west the full tide of emigration. She may be literally said to have become the "fruitful mother of empires." Her population and capital, almost as fast as they have increased, have been swept off by this tide to the distant west, and the soil of Virginia has been left comparatively naked and unimproved, whilst this mania has been operating. Is there a young man of promise, upon whose education the kind father has almost exhausted his resources? How apt is he, when he arrives at the age of maturity, to ask for his little patrimony, and move off to the far west. And the hardy laborer, whose strength and industry constitutes his only property, is disposed to follow on in the same direction, where imagination presents in brilliant colors to his view, ample fields and large domains which are to be *all his own*, and where, in the decline of life, he is to enjoy sweet contentment in the lap of luxury and ease.

The evil effect which this emigration has produced on the condition of Virginia is almost incalculable. It is one of the principal causes of our stationary condition, and of the great depression in the price of real property.

The injury resulting from this emigration is much more than in proportion to the mere numbers who leave us. In the first place, the great majority of emigrants consists of males, who are all over the world more productive laborers than females, and these males are generally between eighteen and thirty, at that period of life when their labor is worth most to society. Up to the age of eighteen, generally, the individual is what the economists call an unproductive consumer, and therefore a burden to the state.

In the second place, the laborers who emigrate are generally among the most efficient and enterprising, because, as a citizen of the west once observed to me, in his strong but unpolished language—"it is only the most energetic and hardy who can boldly resolve *to pull up stakes* and move from their homes."

In the third place, many young men whom we lose by this emigration to the west, are those upon whose education there has been made considerable expenditure, and who are always to be ranked among our most valuable citizens, both in a moral and politico-economical view. The man who in any of the learned professions is making $2000 by the exercise of his talents, is worth in an economical light, four times as much as the simple laborer who earns but $500, and more still in a moral point of view.

In the fourth place, a large proportion of the emigrants to the west take along with them a very considerable amount of the accumulated capital of the state, and this paralizes our agriculture and commerce.

Influence of our central improvement on emigration.

Let us now examine into the probable operation of the James and Kanawha improvement on this tendency to emigration. And first, upon the emigration of western Virginia. For some years past, the emigration from the western and middle counties of Virginia has been as great or perhaps greater than from the eastern. The western portion of Virginia, situated at a great distance from market, possessing roads and improvements of the most wretched character, is necessarily forced to become a grazing country. A grazing country admits but a sparse population—few laborers are required to attend to the cattle. "When the stock is purchased and put upon the pasture (says a very able correspondent from the west)—two or three men can readily attend to several hundred, if sold in November: but if reserved for market in January or February, then a few laborers will be required to raise corn (maize) to feed them during the winter months, which is given in aid of good hay. None can pursue this business with any hope of success unless he has large possessions in land."

Now the effect of this system is two-fold. 1st. to concentrate the property of western Virginia in the hands of a few men—and 2ndly, to produce a redundancy of population, wherever the numbers increase very fast; for as it requires but few to attend to the cattle, all beyond become supernumeraries, and are generally disposed to move off to the great west.

Now what is the remedy for this? Most undoubtedly such a change in the whole labor system as will create a demand not only for all the labor which they now have in western Virginia, but all that they can raise there by the procreative energies of society. The great central improvement will produce this effect. By increasing the facilities of transportation to market, farmers will be encouraged to change the grazing into the grain growing system, because the latter is more lucrative than the former, wherever the productions can be carried to market. "Were a conveyance to market practicable (says the same very intelligent correspondent, from whom I have just quoted) of the usual products of the soil, as wheat, barley, potatoes, rice, &c., the grass farm would soon be divided into several farms for the growing of wheat, which is much more profitable. The five acres of land allowed the ox, if cultivated in wheat, would certainly produce fifty bushels, which would be fully sufficient to manufacture ten barrels of flour, worth at least forty dollars! whereas the beef raised from the same ground would only bring from ten to fifteen—at most, twenty dollars."* It is evident then that the moment you convert the grazing system of the west into the grain growing system, that moment will you produce a new demand for labor. Every new plough which is stuck into the ground will require a new laborer to manage it. This will check at once the emigration from the western portions of Virginia, and will produce, no doubt, an additional demand for labor, which will be supplied most readily from the slave population of eastern Virginia. The effect of this will be most happy. It will, by the diffusion of our slave population over the tramontane regions, add to the wealth and prosperity of that whole country, whilst it will give a homogeneous character to our population, and destroy that dangerous discrepancy of interest, whose baneful operation was so decidedly felt in the convention of Virginia, and which, if it continue, will produce the most unhappy and even disastrous effects.

But again: the influence of our central improvement in checking emigration from eastern Virginia, will be almost as great as that which is exerted on the emigration from the western portion. The immediate effects of the improvement will be to pour the immense productions of the west down upon our Atlantic borders, for exportation. This will necessarily produce a great importing and exporting business—a large town, with many smaller ones, must spring up somewhere within our limits—capital will flow into these towns and spread itself over the adjacent country—the towns themselves will create a new and great demand for the productions of the lower country—the whole system of tillage will be changed by the beneficial operation of this state of things—the garden cultivation will take the place of the grain growing system in the neighborhood of the towns, and diffuse an increased prosperity every where. "The farms of Long Island," says Professor McVickar, "are now turned into gardens, and this not by being driven from their old employments, but by the superior temptations of the new—fruit and vegetables gradually taking the place of butter and grain, and thus creating a new demand for land of the next grade of contiguity. This position may further be illustrated by the history of the supply of fat cattle for the New York market. A century ago they were raised on farms adjoining the city; they are now principally raised three hundred miles from it—driven step by step, through the superior profitableness of the new crops demanded by the increasing extent and trade of the metropolis."* So will it be with lower Virginia. The large farms will be broken into smaller ones—these smaller farms will give an increased employment to free labor, while the towns themselves will increase the demand for the same kind of labor much more than for slave. This will check the tide of emigration among the whites, and keep our population at home.†

Thus this great improvement is eminently calculated to check the emigration from both the eastern and western extremities of our state, and keep our increasing population with us. Now I have no hesitation in affirming that this single effect will be worth to Virginia more than the whole improvement will cost. It will raise the price of lands throughout the state—it will increase and multiply the occupations and trades of the community—it will introduce manufactures, cause a rapid improvement in our agriculture, and change the whole aspect of our state.

The immediate effect of the improvement will be to raise the price of labor in another manner likewise. It will cause in the next five or six years the expenditure of millions of dollars along the line of the improvement. This expenditure will increase enormously the demand for labor, and will raise the hire of negroes throughout the state, besides attracting to it free laborers from all quarters. I wish my limits and time would allow me to show, by numerous examples furnished by the history of canals, rail roads, &c. both in this country and Europe, the immense advantage which

*This letter was written in 1832.

*A gentleman from Missouri assures me that a large portion of the cattle for the New York market is now raised in that state, a thousand miles off.

†As the slave is paid for when carried out of the state by a slave dealer, this emigration does not injure the state, because an equivalent value is left behind: unless indeed where the ready sale of the slaves stimulates the seller to sell his land likewise, and take the whole capital with him to the west.

has resulted from the mere expenditure of money in the construction of the improvement. Population thus attracted to the state will frequently form ties within our limits which will make them a permanent accession just at a time when we stand most in need of them.

If every dollar expended in our state on the James and Kanawha improvement could have been procured from abroad at the rate of four or five per cent., I have no hesitation in saying, it would have been better for Virginia to have borrowed the whole sum instead of raising it at home by subscription. For I have no doubt that the tolls on the improvement will ultimately pay much more than interest on the money expended. And we know too that so soon as the line is in full and complete operation, the price of property, and the profits of stock will rise throughout the state—new employments will spring up—increased energy and activity will be communicated to our population every where, and there will consequently be a new and rapidly increasing demand for capital. Hence the greater disposable wealth in the hands of the people, the greater their prosperity at such a time.

I do not however, by the remarks made, wish to be considered as censuring those who favor the joint-stock scheme of our state. It was the only plan perhaps which could have been successfully carried through, and therefore ought certainly to have been supported rather than leave the state without any improvement at all. There are many other advantages which will result from this improvement, but as they do not fall within the limits which I have prescribed for myself in these brief remarks, I will here draw them to a close.

PHENOMENON.

By a gentleman recently from Prince William county, Virginia, we have been informed, (says the Georgetown Metropolitan,) of a remarkable occurrence which took place on the Neabsco tract, about four miles from Dumfries, on Monday sen' night, during that heavy thunder storm, which, it will be recollected overspread the whole heavens, and apparently visited every quarter of our country. The earth for several acres, which was previously firm and good, *suddenly* (from its present appearance) sunk to the depth of about four feet, and cracked open in innumerable places throughout the whole mass, as if it had been blown by gunpowder. The thunder and lightning which here was comparatively slight, there was awfully heavy and severe, accompanied by an abundant shower of hail, which however, was not so injurious to the grain as to the window glass. Numerous persons have visited the spot, but are totally unable to account for the remarkable phenomenon. Some suppose it to have been produced by the shock of an earthquake, although the people residing in the neighborhood experienced, or rather observed no sensation during the storm to justify such a conclusion; yet it is possible such might have been the fact, as from the continual blaze of lightning and the heavy peals of thunder, with a combination of apprehension for their personal safety, they might have had the shock of an earthquake which they attributed to the effects of a raging storm.

EXTRACTS FROM AN ADDRESS TO THE ESSEX COUNTY AGRICULTURAL SOCIETY.

By Ebenezer Moseley, President of the Society, *September* 25, 1834.

Unsettled opinions on Agriculture.

The art or science of agriculture, if examined, will be found to be as far removed from certainty as the law. That is, there is not any settled opinion as to the means of producing the best results. Agriculture, in its highest state of improvement, must be the result of long experience. The great utility, therefore, of agricultural societies, is, that they call forth to public observation the experience and practice of those, who have been most successfully engaged. Yet it is not a little surprising that agriculture, which was coexistent with man, which has passed through all the successive ages and generations of men, which has had the knowledge of this long experience reflected upon it, is yet, probably, in its infancy, and involved in much uncertainty.

I will illustrate this idea of its uncertainty by taking the cultivation of corn. One would naturally suppose, that the long experience among us in the cultivation of corn, would have settled down in establishing in the minds of all men, some fixed and settled rules as to every part of its cultivation. Yet we find that such is not the fact. I begin with the planting of corn. It is not yet well settled, whether the moon has an influence upon vegetation. Some plant without regard to the moon, and some are very careful to plant only in certain stages of the moon. Some recommend soaking and even sprouting the corn before it is planted, others think it does as well without. Some advise planting in hills, while others think a better crop is produced by planting in rows. Some place the manure over the corn, some place the corn over the manure, while others spread the manure over the ground. With respect to hoeing the corn, some think the corn should be hoed while very young, to destroy the weeds, yet others prefer the corn should remain and the weeds grow up till they get to some height. The reason assigned is, that the corn is less liable to be destroyed by birds, squirrels and worms. Some are of opinion that no hill should be made about the corn, while others deem the hilling the corn to be attended with much benefit. Some practise taking the suckers from the corn, while others severely censure this practice. Some are of opinion that the stalks should not be cut until the corn is sufficiently ripened to be gathered; others are of opinion that cutting the stalks* after the farina has fallen, does no injury to the corn, and affords an excellent fodder for cattle in the winter.

Such are some of the various opinions which have been advocated relative to the cultivation of corn. It is not my design in mentioning them, on this occasion, to speak discouragingly of the art of agriculture. My more immediate object is, to show the importance of greater exactness and closer observation on the part of those, who turn their attention to the subject of agricultural experiments.

* * * * *

* Above the ears, is meant—or "tops" as called here.—Ed. Farm. Reg.

Influence of Agricultural Publications.

The improvement which has been made within a few years in the art of agricultural implements, must be highly gratifying to every farmer. Who, forty years ago, would have thought it possible to raise one hundred bushels of corn on one acre of ground? Yet now, it is no uncommon case for a farmer to raise a much greater crop. This improvement must be attributed in a great measure to the influence of the press. If we go back but half a century, I believe we shall find no periodical publication either in Europe or America which treated exclusively on the subject of agriculture. The consequence was, that in those districts, where particular branches of husbandry were the most successfully and judiciously treated, the knowledge remained with them, unless, perhaps, slowly communicated from one to another, as accident or opportunity should offer. But when journals, devoted to this art, began to be put in circulation, containing the experience of intelligent, learned and practical men, the improvement in particular districts became very generally disseminated. It is true indeed, that in many cases these publications were coldly and reluctantly received, from a false notion, that book learning, especially when it contradicted the opinion they had derived from tradition, must be very visionary. The light of truth has in a great measure removed these errors, and a new era has commenced upon the subject. The knowledge which has been derived from science and experience in one quarter of the world is communicated by the press to all others, and that which was claimed as private property is now communicated for the benefit of all. One fact will strikingly illustrate this subject. When Mr. Knight, president of the London Horticultural Society, sent his first present of new pears in 1823 to Mr. Lowell, his letter and the list which accompanied it, were published in the Massachusetts Agricultural Repository. Within twelve months, application was made for these fruits, and scions were actually distributed from the lower part of Maine to Cincinnati in Ohio.

Among the great improvements which have been made in tools and implements of husbandry, the plough may be mentioned as an instance. Such have been the great improvements in this article, within a few years, that I am told one yoke of cattle will do the work, in one day, which formerly required two yoke, and will do the work, much better. Our ancestors used the flail to thrash out their grain, but modern invention has produced a machine, moved by horse power, and thrashes out as much grain in one day, as one man can thrash in ten days with a flail.

A rake has been invented, moved by horse power. It is said that by this horse rake one man with a horse will put the hay into windrows as fast as eight men can put it into cocks, after it is raked. Among the wonders of the age steam has been applied with surprising success in propelling vessels on water and wagons on land: but in my wildest flights of imagination, I had never conceived the idea that steam could be applied to agricultural purposes. Yet Professor Rafinesque of Philadelphia, a gentleman of great scientific attainments, advertises for farmers his steam plough, by which six furrows are ploughed at once, and which he says will in one day perform the work of a single team for a week, and in the best manner. What a delightful contemplation. How wonderful is man! May we not indulge the hope, that the day is not remote, when all agricultural operation will be performed by steam.*

* * * * *

On the best season to cut timber—Influence of the moon on vegetation.

There is one subject, connected with forest trees, upon which there appears to be a diversity of opinion, and which I wish to present to your consideration, that you may compare it with your own experience. It is, as to the best time to fell

---

*The discovery referred to above was advertised as follows, on the covers of the New York Farmer—

"STEAM PLOUGHS.—Professor Rafinesque, of Philadelphia, offers his services to introduce the use of steam ploughs in the United States. If there is a wealthy farmer who owns level land, and has patriotism enough to connect his name with this wonderful invention, whereby six ploughs can be driven, and six furrows cut, as easily as one now, and one day's labor do the work of a whole week—let him apply to me, and I will enable him to have such a steam plough made for himself and all his neighbors, thus setting the example of this wonderful application of steam."

We, like Mr. Moseley, hope that signal benefits will hereafter be derived from the application of steam power to agricultural processes—but would nevertheless advise that but slight reliance should be placed on the labors of Professor Rafinesque for this purpose—as he has been remarkable for ill success (to say no more) in bringing his numerous and wonderful inventions into use. For example—the same paper from which the foregoing is copied, contains the two following advertisements, which, (with another offering to save many millions by a substitute for railway transportation,) were long published to invite the attention of the heedless and obstinate public. Yet it seems that nobody has availed of these magnificent offers of insurance; and houses are still burnt as often as heretofore, ships sunk, and steamers blown up, without the least regard to Professor Rafinesque's benevolent plans, and splendid discoveries.

"INCOMBUSTIBLE ARCHITECTURE.—Incombustible dwelling-houses and buildings of all kinds devised or built in New York, or any part of the United States, as cheap as any other combustible buildings. Actual buildings and houses rendered incombustible at a small additional expense.

Ships of all sorts, and steamboats, rendered incombustible, and not liable to sink, at a small expense.

For sale, 10,000 lbs, of Antignis, or Incombustible Varnish, at one dollar per pound.

Apply to C. S. Rafinesque, Professor of Hist. and Nat. Sciences, Chemist, Architect, &c , in Philadelphia, No. 59 North 8th street. A pamphlet given gratis."

"TO STEAMBOAT COMPANIES.—Professor Rafinesque, of Philadelphia, offers his services to render steamboats incombustible, and not liable to sink, even by the bursting of boilers, or striking against snags, sawyers and rocks. This will save many boats, much property, and the lives of hundreds every year. Those who neglect this easy improvement, deserve to be neglected and deserted by the public as unmindful of safety. Apply, post paid."

timber, with a view to its durability. To me, it is a matter of much surprise, that the opinions of practical men are not uniform and settled upon this subject—a subject so important to almost every man in society, and particularly to those who have any interest in civil and naval architecture. The subject appears to be as unsettled in Europe as in this country, or rather the prevailing opinion in both countries is probably erroneous. It appears to be the more general opinion in Europe and in this country, and the practice has conformed to this opinion, to fell timber in the winter, or while the sap is down; or to be more precisely accurate, in the month of February in the old of the moon. In France, by a royal ordinance of the year 1669, the time of felling naval timber was fixed from the first of October to the fifteenth of April, in the wane of the moon. Napoleon, having adopted the opinion that ships built of timber felled at the moment of vegetation, must be liable to rapid decay, and require immediate repairs, from the effects of the fermentation of the sap, in those pieces which had not been felled in the proper season, issued a circular order to the commissioners of the forests, that the time for felling naval timber should be abridged, and that it should be in the decline of the moon, from the first of November to the fifteenth of March. Commodore Porter, of the American Navy, in the communication which appeared in the American Farmer, gives it as his opinion, that the most proper season for felling timber, with a view to its durability, is in the winter, when the sap has ceased to circulate. He is of opinion that the moon has a powerful influence upon timber, as well as upon many other things.

Notwithstanding this powerful array of authority for felling timber in the winter, while the sap is down, to increase its durability, many experiments have been made which seem to establish the fact that timber cut when the sap is in most active circulation, is most durable. Mr. Benjamin Poor, the owner or occupant of Indian Hill Farm, in this county, in a communication to Gorham Parsons, Esq. published in the Massachusetts Agricultural Repository, states the following fact as within his own knowledge and observation. His grandfather, in the fall of the year 1812, selected two white oak trees, size, situation, general appearance as to age and health and the soil, as near alike as possible. In the month of March following, in the old of the moon, one tree was cut, the timber carried to the mill and sawed into suitable timber and scantling for an ox cart, and put it up to season in the open air. The middle of June the other tree was cut, carried to mill, and sawed as the former, suitable for an ox wagon, and put up in the open air to season, and treated in every respect like that cut in March. In the fall of the year, both parcels of timber were housed, and in the spring following an ox cart was made from one, and an ox wagon was made from the other parcel, both painted, and the work alike in all respects. They were used principally for hauling stone, and if there was any difference in the service to which they were used, it was that the June timber had the hardest. They were both housed in the winter and commonly remained out in summer. Mr. Poor says, at this time (1821) the one made of timber cut in March is very much decayed, the sides defective, much bruised, and a general appearance of decay, while that made of timber cut in June is perfectly sound, has not given way nor started in the joints, or in any respect appears half as much worn as the other, although it has had the hardest service.

The late Hon. Timothy Pickering, the first president of our society, whose zeal and intelligence, connected with his long experience and great industry, give to his opinions much value, appears to have been of opinion, that the best time for felling timber trees for durability, is, when the sap is vigorously flowing. He states the following fact, as communicated to him by Joseph Cooper, Esq., of New Jersey, a practical farmer. Mr Cooper's farm lay upon the banks of the Delaware, nearly opposite Philadelphia, and was exposed to the ravages of the British army while occupying that city. Pressed for fuel, his fences first fell a prey to their necessities, and in the month of May, 1778, they cut down a quantity of his white oak trees; but circumstances requiring their sudden evacuation of the city, his fallen timber was saved. This he split into posts and rails. The ensuing winter, in the old of the moon, in February, he felled an additional quantity of his white oaks, and split them into posts and rails to carry on his fencing. It is now, said Mr. Cooper, twenty-two years since the fences made of the May fallen timber were put up, and they are yet sound; whereas those made of trees felled in February, were rotting in about twelve years. Mr. Pickering treats the notion, that the moon has an influence upon timber or vegetation, as visionary.

I have before said, that it is not yet well settled whether the moon has any influence upon vegetation. It is, indeed, a singular fact, that this subject should remain unsettled even to the present day; and yet it is so far unsettled, that probably one-half of our farmers who have occasion to sow a field of turnips, would prefer the old of the moon. I have never had any belief in the supposed influence of the moon, and have generally adopted the opinion, that industry and sunshine will be very well without any aid from the moon. I have generally ranked this opinion of the moon's influence, with those superstitions which would give importance to the circumstance, whether the moon was first seen over the right or left shoulder, or whether an enterprise would be successful commenced on Friday. And yet some men of great science and experience are firm in the belief of its influence.

It would be an amusing exercise to collect the various opinions and facts, both ancient and modern, upon this subject, but it would far exceed the limits of this discourse. I will however remark, that the ancients paid great regard to the age of the moon in the felling of their timber. Their rules appear to have been to fell timber in the wane of the moon, or four days after the new moon; some say let it be the last quarter. Pliny orders it to be in the very article of the change, which happening in the last of the winter solstice, the timber he says, will be immortal. Columella says, from the twentieth to the twenty-eighth day. Cato, four days after the full. Vegetius, from the fifteenth to the twenty-fifth for ship timber, but never in the increase: trees then much abound with moisture, the only source of putrefaction.

Commodore Porter, we have seen, is of the opinion that timber should be felled in the old of the moon to give it durability, and he expressly says that its influence is nearly, if not quite as powerful as the sun. The commissioners of the French forests require such timber to be cut in the old of the moon, and such has been the standing regulation from the year 1669.

Mr. Staples, of Turner, in the County of Oxford and State of Maine, in a communication in the New England Farmer, describes himself as above the age of seventy years, and during the greater part of that time has been a practical farmer. He removed to this place at the age of twenty-two, when the country was new, and was among the five first settlers, and has given particular attention to the moon's influence on timber, vegetation, &c. He says, that it is a truth, that the moon operates upon the earth and every thing which grows upon it, much more powerfully than is generally imagined. It is also true, that the effects of her operation vary regularly, as she passes through her orbit or monthly course. Timber, cut in the wane of the moon, will be much more durable than it would be if cut between the new and full moon. Her operations are so great and different in the various parts of her orbit, that by cutting one tree three hours before the new moon, and another of the same kind six hours afterwards, and preserving them one year, a very striking difference in the soundness of them will be discovered. If I had known, says Mr. Staples, as much at the age of twenty-two years, as I now do, relative to this subject, I am satisfied it would have benefited me more than a thousand dollars, particularly in clearing hard wood land and in getting durable timber for buildings of all kinds, and for sleds, carts, &c.

He says, I have found by experience that fruit trees set out in the wane of the moon, and particularly on the last day of the last quarter, are more likely to live and be flourishing, than when set out at any other time. I have proved by experiments for ten years in succession, that an apple tree limb or graft, cut off in the month of May, about three hours before the moon changes, and carefully set out, will grow and do well.

Another writer says, that in the months of May, June, and July, oak trees, in the new of the moon, will readily part with the bark, when, in the old of the same moon, the bark will adhere closely.

Such are some of the opinions and facts to support the affirmative of this question; but opposed to these opinions may probably be found most of the scientific and practical agriculturists of the present day. Doctor Dean and Colonel Pickering, men of great experience, practical knowledge and accurate observation, consider these notions of the moon's influence as visionary. There are certain operations of the moon upon the earth, which are obvious and admitted by all. It affords us light by night, it turns the earth in some degree from its elliptical orbit, it occasions a small oscillation in the earth's axis, it causes the ebbing and flowing of the sea, and a like effect upon the atmosphere. But heat, which is the cause of vegetation, has never yet been discovered in the collected rays of light from the moon. Experiments, made at the Royal Observatory in Paris, have proved, that the light of the moon condensed by a powerful lens, had no effect whatever in altering chemical products, though very sensibly and easily affected by the light of the sun. Another fact is, that the most opposite weather in different parts, take place at the same instant of time, and of course under the same phases of the moon.

It was probably from opinions prevalent in the days of Solomon of certain influences in the heavens, that he was led to make the mild rebuke—"He that observeth the wind shall not sow, and he that regardeth the clouds shall not reap."

From the National Intelligencer.

UNION GOLD MINING COMPANY OF VIRGINIA.

A party of Cornish miners arrived at New York, a few days since, in the ship Boston, of London, and passed through Philadelphia on their way to the Company's Mines. We are informed also, that a large amount of machinery, of the most approved construction, is expected daily. It is gratifying to perceive that the attention of British capitalists has been at length awakened to the great mineral resources of the southern states. It is natural to suppose that native American enterprize will derive much advantage and information from the well-directed operations of the London Company, whom it may be presumed have been very choice in their selection of men and machinery, and from the known success of the Brazilian Mining Company, whose profits amounted to $250,000 per annum. These foreign capitalists may reasonably calculate on a largely profitable return. We now confidently anticipate some fixed results, which will more completely develope and satisfactorily determine the character of the gold region of the southern states. The future conduct of similar operations must be much modified and directed by the successful results of the present undertaking. The skill and science which will be here evinced, cannot fail to save many engaged in similar enterprises from much useless expense and disappointment.

From the New Monthly Magazine.

CAUSE OF FAILURE OF THE POTATO CROP.

Mr. Hickley has communicated to the "Irish Farmer's Journal" a very singular and successful experiment tried upon the potato in the county of Dublin. A gentleman who holds a farm of 150 acres, planted in the usual manner 34 acres under potatoes in 1832; the result was, a complete failure of the crop. This induced him to try many experiments upon the root, all of which failed except the following: he took six potatoes and divided them into twenty cuts; he then got a large basin of water, into which he put a cupful of salt and a piece of blue stone about the size of a walnut. He put ten of the cuts into the basin, and let them remain there one entire night. On the following day he procured a very strong microscope, through which he examined the entire twenty cuts. On the ten cuts which were not immersed in the basin he could distinctly perceive many small white particles like eggs; and those cuts which were not immersed presented no such appearance whatsoever. This discovery urged him to follow up the examination attentively; and every day for a short period, he continued to watch the appearance of the aforesaid matter. The result was, that those white globular particles were animalculæ, for in a few days they became quite visible to the naked eye in the form of worms or maggots. The cuts that had been steeped never showed the slightest appearance of any such thing; and they retained their solidity and firmness when the other ten cuts were completely decayed and rotted. Still unwilling to believe without further proof, he tried the experiment five or six times, and planted them, distinctly marking a division between those cuts which were steeped and those that were not. The consequence was, the almost total failure of one kind and the complete success of the others placed the question beyond the possibility of a doubt. He considers that the air has a powerful effect on the potato, and may sometimes impregnate it with this destructive matter.

From Scientific Tracts.

HAMMERING STONE.

A physician of this city has invented a machine, recently patented, for hammering and facing granite, or any other kind of building stone. The mechanic who constructed a model for the patent office, at Washington, informs us that he considers it in the light of a happy discovery, as faced stone may be shortly afforded as cheap as brick. A number of hammers, weighing not far from twelve pounds each, are set in motion either by steam or water power and move with such rapidity that the fragments fly like dust in a windy day. All the hammers move diagonally across the stone, in two directions, thereby completely levelling and smoothing it by simply passing the block onward under them and back again. One of these machines, on a large scale is being erected at South Boston. Should it answer the expectations of the inventor, the old fashioned method of hammering stone will be wholly neglected as one machine will accomplish as much in a day as twenty or thirty men.

[A wiseacre who conducts a northern paper boasting of some 20,000 subscribers, after publishing the foregoing statement remarked that "this is very well —*provided* that the money saved by the invention shall be given to the stone cutters thrown out of employment by the use of the new process." Having mislaid the paper, we quote the words from memory and therefore probably not exactly—but the luminous idea is not stated incorrectly. Its promulgator is a true supporter of the principles of the restrictive policy—of the protecting duty school: and the same views would have prohibited the first use of ploughs and mills—and in short, every labor-saving implement and process that have benefited the world, and have served to distinguish men in the civilized, from the savage state.]

From the Troy Whig.

BURDEN'S HORSE SHOE MACHINE.

The mechanical skill and inventive power of our townsman, Mr. Burden, appears to be in constant and active exercise. We had the pleasure of examining, a few days since, at the Troy iron and nail factory, a recent invention of his for the manufacture of horse shoes, which, for curious mechanism, and practical importance, is equal to any thing which the genius of *constructiveness* has produced for many years. By the operation of this machine, a heated bar of iron is converted —as if almost by magic influence—into horse shoes, of any size that may be required, that for cheapness, neatness, and smoothness of external appearance—firmness of texture, and practical utility, are greatly superior to the article now in general use. The admirable adaptation of the machine to the purposes for which it is intended, and the great rapidity with which it operates, is truly wonderful.

Extract from Featherstonhaugh's Geological Report, Published by order of Congress, 1835.

ACCOUNT OF THE LEAD ORE, AND MINES OF MISSOURI.

* * * * I became now desirous of finding some natural sections that would assist in explaining the phenomena around me, but I could find none, and could hear of none, so that it became necessary for me to examine the localities where mining operations were conducted, in order, by an examination of the subterranean arrangement of the metallic beds, to form some estimate of their direction and extension towards those parts of the country where the public lands lay. I accordingly visited the most ancient "diggings" which had been partially carried on ever since the French had had possession of the country, but I found that the irregular manner in which those diggings had been conducted almost baffled every attempt at systematic investigation. The sulphuret of lead, or "mineral," as it is called in the lead country, has been, in certain localities, at all times found in fragments near the surface of the ground, from the size of a pin's head, in which it can be picked up in great quantities where the rain has washed the soil, to masses weighing several hundred pounds. Sometimes pieces of an intervening size are found, which have been affected by attrition; but, more frequently, the "mineral" preserves its angles very fresh, as it might be expected to do from its brittle cubic structure. Various opinions have been entertained of the cause of so singular a distribution of this mineral substance in loose pieces, and occasionally in such great quantities, near the surface of the earth—a circumstance which has occasioned the whole adjacent country where the mineral has been found, to be excavated into pits from six to twenty feet deep, so that in the localities of such districts it would be impossible to drive any carriage by daylight, and impracticable to ride securely on horseback by night. The disorder into which the country has been thus thrown, is entirely owing to ignorance of the geological structure of the country, and the commonest principles of mining, and is much to be regretted, as it will greatly embarrass future efforts, in those localities, at systematic mining. It would be superfluous to enter into any mineralogical detail of those diggings, or to render a very particular account of any of them, since nothing can be more rude than the attempts at collecting ore which they exhibit. In particular localities immense quantities of sulphate of barytes, or "tiff," as it is named, masses of quartz rock, cellular, and occasionally coated with mammillary crystals of great brilliancy, and, in other instances, a pro-

fusion of dark red clay, are thrown out of the diggings, together with the mineral.

It was at Mine la Motte I first received satisfactory evidence that the broken up mineral I had seen in the diggings had been occasioned by an accidental derangement of the regular structure of metallic veins, and to which I had always attributed these appearances.

The country around presents an extensive table land, almost denuded of timber, through which a few slight streams run, which are used to wash the soil taken out of the shallow diggings. The whole surface is cut out into pits of various sizes, from four feet diameter to some exceeding twenty feet square, with an equivalent depth. These larger areas have been the result of a discovery gradually made, that the loose fragments near the surface, which were formerly the sole object of the diggings, were connected with *mineral* imbedded in the solid rock. Hence, large areas have been opened, without much relation to method, sometimes to the extent of half an acre, and gunpowder is employed to blast the metalliferous rock; so that mining in this particular district is become precisely what quarrying is every where else. The history of these diggings, and the manner in which the sulphuret of lead is often found, is as follows. The streams washing through the superficial gravels sometimes disclose valuable deposites of the ore. Adventurers follow up these indications wherever found, and commence their diggings: when they reach a depth of twelve or fifteen feet, or as soon as it becomes inconvenient to throw out the earth, or hoist out the mineral, a new digging is commenced, and again abandoned for a new excavation. Frequently the superficial soil for about a foot will be red earth, mixed with mammillary quartz, called here "mineral blossom," and petro-siliceous stones; a deposite of red clay of a few feet is then generally found, resting upon a bed of gravel and flinty pebbles, in which the lumps and fragments, including extremely small pieces of ore, are found. Deposites of this kind do not differ, in any particular of mechanical arrangement, from any gravel deposites I have seen, especially the gravel deposites of gold in the southern states, and which are, without exception, the detritus of rocks brought into these superficial beds by aqueous transportation. Beneath these free deposites lies the real metallic formation of the country, consisting of the fetid calcareo-siliceous rock before described, frequently so much decomposed as to admit of being shovelled out, and traversed by horizontal bands of bright galena, or sulphuret of lead, sometimes one inch thick, and frequently a foot thick. In other situations, the ore is very much disseminated in the rock, although always confined in a vein or bandlike breadth, of different dimensions. Where the ore is much disseminated, and the rock is speckled with metallic particles for a great breadth, the ore is usually less productive, yielding about forty or fifty per cent. of lead, when the compact mineral in other situations yields sixty-five per cent. Upon such occasions it appears to contain an excess of sulphur. In some instances, I observed broad veins with a considerable dip, but generally the bands of ore were nearly horizontal. This locality appears to furnish a full explanation of the singular manner in which the ore and sulphate of barytes, in which it is often sheathed, have come into that free and broken situation in which they are found in the superficial deposites. I observed veins at the top of the metalliferous formation, and beneath the superficial deposites, in quarries fifty feet across, and twenty feet deep, containing fragments of ore of various sizes, bright and sharp, with the vein, as well as that part of the rock through which it passed, much shattered and dislocated, the back of the vein being broken in numerous places, and the contents exhibiting strong marks of sudden violence. Sometimes the galena was rent in shivers, sometimes its horizontal sheet was broken up, and parts of the bright ore, ten inches wide, left standing on their edges, some in one direction, some in another, and the remainder left flat in its old place. In some places the phenomena resemble those presented in the chalk cliffs near the Isle of Wight, in England, where the beds are upset, and the seams and nodules of flint shivered. This is not the case, however, with all the veins. In various quarters at Mine la Motte, especially those which go by the name of Mine la Prairie, where more than half an acre of ground has been uncovered to a depth of twenty feet, the sulphuret of lead is not only seen running horizontally in hard compact veins in the calcareo-siliceous rock, but is sometimes disseminated for a great extent, in specks through the rock, affording to the eye sufficient proof that the stony and metallic matter was deposited at the same time; for if either of them were abstracted, no principle of adhesion would be left for the remaining mineral: occasionally the rock changes its character, becoming either calcareous or siliceous altogether, and, indeed, the structure differs so much as to be sometimes hard, sometimes soft, sometimes granular, sometimes compact. Sometimes a bed of sandstone, three feet thick will lie upon a seam of bright mineral six inches or a foot thick, though more generally it is much thinner, and lies in a flat plate. I have however, seen it in veins of two feet thick. The deepest digging or quarrying I observed at this place did not exceed twenty-five feet; they had not yet begun a regular system of sinking shafts and cutting out drifts, but no doubt this will soon be done, as both the public and private lands around the whole region of Mine la Motte are, in my estimation, underlaid by rich veins of galena, that descend very deep towards the central parts of the earth. The superficial indications of this mineral are unerring.

On the approach to a mineral district, numerous localities present a confused, but distinct and rather unvarying character of crystallization. Imperfect nodules of siliceous matter, masses of mammillary quartz, the crystals of which are often superinduced upon chalcedonized concentric layers with an agate structure, indications of sulphate of barytes, with small fragments of sulphuret of lead in the rain furrows, betray the metalliferous rocks: these are the situations which are chosen to commence new diggings in, and with invariable success as far as respects the finding ore. But from some works which have been recently constructed, and which I had an excellent opportunity of examining, I am confident a thorough reform in the whole system of mining in that interesting country is about to take place, and that it will henceforward be conducted upon acknowledged principles, consistent with the true nature of metalliferous veins, and that economical administration of the mines which will enable them to contribute powerfully to the national resources.

These works, which, when I visited them, belonged to Messrs. Taplit and Perry, are distant four or five miles from Vallée's mines and about twenty-five miles from the point where I observed the quartzose sandstone jut out into the Mississippi. They are situated in a small valley at the foot of a ridge of calcareo-siliceous hills, and abound in the external indications I have before described. The proprietors, disregarding the superficial ores, and confiding in the metalliferous nature of the rock formation, had boldly sunk a shaft, in imitation of some practical miners from England, on the other side of the hill, and had been rewarded with the most perfect success. In sinking this shaft, they had come, at random, at a depth of about sixty feet deep, through decomposing calcareo-siliceous rock, upon a vein of sulphuret of lead, and going down, had reached another horizontal vein upwards of one foot thick, and throwing out from it numerous subordinate veins and threads, into all of which they had cut drifts, wherever the mineral was sufficiently abundant. They had sunk this shaft to a depth of about one hundred and ten feet, when I was there, and very obligingly let me down into it, and gave me every aid and facility in examining their works, which enabled me to observe the very curious structure of these metalliferous rocks, and to form a satisfactory opinion of the geological structure of all this remarkable country.

In pursuing the maine horizontal vein, I came, in succession, to a great number of cavities or pockets—analogous to those of some parts of the gold region in Virginia—in the calcareo-siliceous rock, of various sizes. Some of these caves, as they are there called, are not more than four or five feet across, whilst others are much more extensive. I examined one which was about forty feet from top to bottom, and about thirty-five feet in diameter. The uniform horizontality of the veins would keep the true nature of their origin in great obscurity; but, before I reascended, I had an opportunity of examining what they called the *main channel*, which proved to be an almost vertical vein, filled with compact galena, and about eighteen inches broad. I found the course of this lode to be about N. N. E. and S. S. W., with an inclination of about 18°; and upon examining it further, and reviewing what I had seen before, I had no longer any difficulty in understanding that these horizontal veins, and their subordinate ones, were lateral jets from the main lode, after the manner that Mr. McCulloch has described the structure of the horizontal injections of trap rock into sandstone at Trotternish, in Scotland.* Having made these observations upon the direction of these veins, I commenced an examination of their structure more in detail, and found they were all what is called in some of the mining districts of England *wet veins*, being, without exception, encased, not in sulphate of barytes, but, in pure brigh red argillaceous matter, quite wet below, and cutting with a bright waxy face. This red clay accompanies the galena wherever it goes, always including it as in a sheath, and carrying along with it sometimes nodules of quartz, and of iron, zinc, and galena, which last compound is called by the miners *dry bones*. Every one of the pockets or cavities was filled with this red clay, even the large one I mentioned; but at the bottom of each of them was a thick bright plate of sulphuret of lead, that seemed to have sunk to the bottom by its specific gravity. All these circumstances seem to point to a projection of this metallic and mineral matter from below.* At these mines, when circumstances are favorable, they can raise and bring to the surface, as I was informed, five thousand pounds of the mineral a day —a quantity that could be easily quadrupled if the demand for the metal justified it. This sulphuret yields sixty-five per cent. pure lead of commerce. I had occasion to observe, in numerous instances, that the mineral indications on the public lands were quite as encouraging as at the established mines; but this mineral of lead, to judge from obvious appearances, exists in such inconceivable profusion in the metalliferous region of the south of Missouri and the north of Arkansas, that, like the iron of which I am about to speak, it may be relied on for countless ages as a source of national wealth, and an interminable supply of the most useful metals.

* Vide McCulloch's "Western Highlands of Scotland."

* During the eruption off Sicily, in 1832, when the volcanic island was formed, the agitated ocean was filled for several weeks with red mud.

From the Same.

REMARKABLE DEPOSITE OF IRON ORE.

Having completed my examinations of the lead mines, I pursued a southerly course, with the intention of visiting the district of primitive rocks, as it had been described to me, which lies on about the same parallel with the heads of the Merrimack river. At a considerable distance I perceived very lofty hills of a different aspect from any I had yet crossed, and having an abrupt and stony ascent. The rocks upon the slope of the chain are for a considerable distance denuded, and present a well defined syenite. The chain at a distance appears to run N. E. and S. W., but, upon crossing it, and examining it inside, it deflected into a crateri-form, reminding me in some of its features, of some ancient volcanoes I had seen. In various portions of this district I found varieties of greenstone, alternating with some horizontal rocks entirely quartzose, and containing no lime. Upon one lofty hill of syenite I found immense breadths of this siliceous rock, extremely and ponderously impregnated with iron; and at a distance of about a mile from this, the iron increasing in quantity in the intermediate distance, I came upon one of the rarest natural metallic spectacles I have ever seen. Upon a mound sparingly covered with trees, I observed a veinlike mass of submagnetic iron, and having a bright metallic fracture, of a steel gray color. This vein was about one hundred and fifty feet above the surface of the adjacent plain, and at the surface had the appearance of being roughly paved with black pebbles of iron, from one to twenty pounds weight; beneath the surface it appeared to be a solid mass. I measured the vein from east to west full five hundred feet, and I traced it north and south one thousand nine hundred feet, until it was covered with the superficial soil. Unusual as is the magnitude of the superficial cubic contents of this vein, yet it must be insignificant to the subterranean quantity. This extraordinary phenomenon filled me with admiration. Here was a single locality of iron offering all the resources of Sweden, and of which it was impossible to estimate the value by any other terms than those adequate to all a nation's wants.* Upon a more minute investigation of the country, I found other similar metallic beds, though not of an equal extent, and all upon the public lands.

Extract from Featherstonhaugh's Geological Report.

NOTICE OF THE PRAIRIES WEST OF THE MISSISSIPPI—THEORY OF THEIR FORMATION.

From the Caddo to Tournois creek, the distance is about fifteen miles, always upon good level soil. Part of the country, however, was sandy, with heavy beds of a bluish green arenaceous clay, containing a trace of lime. I found no fossils or impressions in it, but was induced to believe it was the equivalent of some tertiary beds I had seen near Shirly, on James river, Virginia. The whole of this part of the country almost seems to be underlaid with rotten limestone, derived from broken down marine shells. The country hence for several miles, consists of good bottom land, full of holly and laurel, with occasional hills of old red sandstone of moderate size, with their usual pine trees. Having gone about twenty miles, the country fell again to the south, and I soon came to an important stream which rises to the north west, and empties into the Washita, called the Little Missouri, from its waters being of a dusky red, muddy color. On crossing this stream, I entered upon a dense low bottom of the richest soil, covered with cane, holly, laurel, and swamp timber, intersected by numerous bayous; this lasted for three miles, when the country began to rise a little again; and, after advancing a few miles, I came upon a singularly black waxy soil of a carbonaceous color, entirely different from any thing I had yet observed, except the surface of the travertin, at the Hot Springs, which, as I have before observed, was not dissimilar to this, agreeing further in the profusion of helices and other land shells with which it abounded. The country here appeared to consist of a chain of prairies running westward, and parallel with Red River for a very great distance. Some of these prairies were mere bald spots, of half an acre and upwards, surrounded by plants, whilst others were said to contain several hundred acres. In every instance they were surrounded with a belt of timber and plants peculiar to the country. I was informed by Judge Cross, a gentleman well acquainted with the country, and to whose intelligence and hospitality I owe many obligations, that these prairies extend probably many hundred miles to the west, and that it is an opinion deserving of being entertained, that plants are encroaching upon the prairies generally. It was with sincere pleasure I found myself upon geological grounds, with which I was well acquainted. The prairies were covered with the fossils which, as I have before observed, characterize the New Jersey green sand formations,* but the superficial soil was uniformly of a deep black color, resembling charred wood, and in wet weather is of a waxy, plastic consistency, that makes it extremely disagreeable to move amongst. Its fertility is remarkable, and renders it eminently fitted for cotton, which, as I had many opportunities of observing, succeeds well. The black soil, which is substantially calcareous, contains, as I found from slight experiments, a proportion of carbon.

This was one of the most lovely countries I had seen, a gentle rolling surface and fine woods, in which is an abundance of the indigenous crab apple,† with the beautiful bow wood,‡ or bois d'arc, as it is usually called. On examining where the streams had abraded the lower parts of the land, and digging in various places, I found that all these portions of the country, which consisted of prairie land, were bottomed upon immense beds of rotten limestone, derived from the testaceous remains of the mollusca I have named, entire shells of which in a soft state are still imbedded in the broken down masses once composed of shells. The zone of black land here does not appear to have a breadth of more than five miles; wherever it is, the same fossils are found, with the undervalves profusely scattered around on the surface. Sometimes the black earth gave place to a deep red marl of great fertility, but in this marl I found no shells; they seemed peculiar to the black prairie land. It was evident I was here upon an ancient floor of the ocean, from which we may infer it had retired with comparative tranquillity, the surface being so little disturbed. The broken down marine shelly matter had accumulated into local beds and extensive hill deposites, after the manner in which we know some existing species accumulate, and the general irregularity of the surface was not dissimilar to that which is presented by the various soundings of marine coasts, where recent surfaces are forming. These accumulations are more or less covered with a vegeto-animal deposite, that, by the constantly acting power of the elements, is partially removed, and carried by rains towards the streams; hence this covering is diminished in some places, and thickened in others. In some situations the black soil is two or three feet deep, whilst in others it is only a few inches thick, in which latter situations the tender roots of plants, having in extreme dry weather, to contend with a caustic calcareous bed, are liable to perish; the Indian corn for this reason, is sometimes what is called fired, its leaves drying up and wasting away. These characteristics of the prairie country, as far as this particular zone of prairies is concerned, is common to a vast extent of country to the west of the points I examined. To the east the zone extends from north latitude 33° 40′ to north latitude 32° 30′, in the state of Alabama§,

* It yields about sixty-five per cent. of fine iron, but is found not to weld easily, which I attribute to an excess of sulphur.

* Gryphæe convexa, exogyra costata, &c. &c.

† Malus coronaria, twenty feet high, ten inches in diameter.

‡ Maclura aurantiaca.

§ Wells, five hundred feet deep, have been dug through rotten limestone, into slate with quartz.

and can be traced at intervals to north latitude 40° 30′, in the state of New Jersey. Throughout this very extended line, all of which I have personally examined, the characteristic shells of this subcretaceous formation have been found. I possess gryphæa, exaggra and other shells, from localities far up the False Washita, the neighborhood of the Kiamesha, from Mount Prairie in Arkansas, from Mississippi, from Prairie Bluffs in Alabama, and from New Jersey, all of them identical; and in the subcretaceous deposites of Alabama, I have found the greatest profusion of the fossil equivalents of the genera peculiar to the green sand beds of Europe. I hope at no distant period to be able to trace, with some precision, the ancient littoral bounds of that geological period, so clearly demarcated by all the unequivocal circumstances I have described.

In relation to those areas which have received the appellation of prairies, from their surfaces, denuded of timber, being at certain seasons covered with long grass, I am not of the opinion of those who think that all prairies have originally been produced by firing the timber annually, and thus, by repeated combustions, destroying the timber as well as the sprouts. That much ground has been denuded by such means, I would admit, and the cause certainly would appear a sufficient one for those prairie districts to which no other cause apparently could be assigned. By whatever method plants begin first to germinate in such deposites, it is evident, as I have before stated, that where the vegetable matter is thin, and the season unfavorable, they are liable to perish; and where they would not altogether perish, it must be remembered that this country was stocked, as the more distant prairies still are, with buffalo, which would, by their periodical occupation of the country in numberless herds, assist in exterminating plants of a vigorless constitution. These may be enumerated amongst the efficient causes of a prairie or meadow state of extensive tracts of country. This view of the subject is somewhat strengthened by the fact of plants, in modern times, encroaching on the prairies; for I have observed they encroach on the sides where vegetable matter has been washed and accumulated, finding a nutritious bed there, into which they can push their innumerable delicate fibres, secured from the devastating teeth and hoofs of the buffalo, which have now all left this part of the country; for where man settles, that animal never remains long. But there is also another view of the subject.

These vast prairies of the west, as well as the diminutive ones in question, must be admitted to be ancient floors of the ocean. When it abandoned them, they were, of course, without plants; and unless we admit their spontaneous growth, we must suppose them to have germinated from seeds derived from plants growing on lands which had been left with a higher level than the ocean, before it receded from these prairies. Their borders would, of course, be planted first, and thus we can conceive of every new generation of plants giving some of its seeds to the winds and the waters, and gradually extending the forests, like the present members of the human family, advancing upon, and settling the country for the uses of posterity. This seems a more natural and just method of accounting for the immense prairies of the west, and the pampas of the southen portion of the South American continent, than conjectural opinions founded on a convenient method adopted by the Indians of securing their game, and which they have practised at all times, certainly with the effect of thinning, but without destroying the timber, as we know from the immense forests of Virginia, Tennessee, Kentucky, Indiana, Missouri, and Arkansas, which were once annually fired by the Indians, to burn the high grass, that they might better see their game—a practice which destroyed the undergrowth, but only thinned the trees; and now that the Indians have left these countries, we find the undergrowth rapidly occupying the ground again. Before we receive opinions altogether hypothetical in relation to the cause of the prairie condition of land, it seems as if we were bound to inquire what was their first condition, consistent with the geological fact that they are ancient floors of the ocean. It, therefore, appears to me to be probable that many of these prairies have never, since the ocean left them, been covered by any vegetables of greater importance than the gramina. Under this view of the matter, it is consistent to suppose, what is personally known to me to be the fact in many observed instances, that trees and plants may be transplanted to those prairies with perfect success.

AMERICAN CEMENT.

The Catskill Recorder thus speaks of this article, which is manufactured by a company in the City of New York:

"The cement, which is at first like ordinary mason's mortar, becomes by age and exposure, as hard as granite itself, and resists the action of frost under any circumstance. We were shown cisterns, well curbs, sections of an aqueduct, and a monument, which were said to have stood in the open air through the last winter, and the summer thus far. These, when struck smartly with a trowel, gave out fire, and a clear ringing sound, which indicates the absence of any flaw. The cement is first moulded, then polished with a trowel, and after it has had time to harden, glass itself could not be more absolutely impervious to water. In all situations where it is desirable either to confine or shut out water, the cement answers every purpose, and is withal as we are informed, a very cheap material. In the process of hardening, it suffers no contraction, and in constructing from it works of any kind, no other care seems necessary than to protect them from being mutilated or defaced; while in a green state. This material is now employed for a variety of uses, and every day calls for its application to some new purpose. We think that it will yet be extensively used in the construction of docks, aqueducts, canal locks and rail roads. The facility with which it may be moulded into blocks of a uniform size and shape, seem peculiarly to recommend it for bed stones on which to lay the rails; and in answering such a purpose, it may very materially reduce the expense of rail roads as at present constructed."

From Meyen's Voyage round the World.

SINGULAR TRADE IN BRAZIL.

Many owners send their slaves for daily employment to the neighboring quarries, while very many others send them out to catch insects: and this is the reason why the most brilliant insects are to be had so cheap at Rio de Janeiro. When a man has attained to some adroitness in this operation, he may on a fine day catch in the immediate vicinity of Rio more than five or six hundred beetles. This trade in insects is considered very lucrative, six millreis (four rix-dollars, or about fourteen shillings,) being paid for the hundred during our stay. There is a general demand for these brilliant beetles, whose wing-cases are now sought for the purpose of adorning the ladies of Europe —a fashion which threatens the entire extinction of this beautiful tribe. The diamond-beetle (chlamys bacca Kert., and especially the chlamys cuprea, Klug.,) was in great request for brooches for gentlemen, and ten piastres were often paid for a single beetle.

PRACTICAL DETAILS OF MANURING—SINGULAR COLLECTION OF SHELLS AND BONES.

To the Editor of the Farmers' Register.

Charles City Co. Dec. 26, 1834.

In compliance with your request that the members of the agricultural community contribute to advance the interests of agriculture through the medium of the Farmers' Register, I have determined to throw in my mite, contenting myself with the reflection that although this communication may fail to afford either interest or pleasure, yet the motive and object will be duly appreciated, and the manner and matter receive the indulgence of an enlightened community.

The farm on which I reside is a gray soil, lying on a substratum of yellow sand, with the clay at the distance of from eighteen inches to two feet below the surface. It had been reduced to the lowest degree of poverty by the system practised by our ancestors, when I came into possession of it in 1823. I immediately cast about in my mind for means and resources for improvement. The object was to sustain my family, and at the same time improve some land. I therefore immediately enclosed a lot of ten acres, which was improved and cultivated in corn and peas for several years in succession. The corn was planted five feet each way, with as many pea hills as corn hills. It was gathered and shucked out as early as the corn would bear gathering, and my hogs turned upon the peas. This lot added from sixty to eighty barrels of corn to my crop annually, whilst the peas assist very much in fattening my hogs. Indeed, I know nothing better than a field of green peas to put hogs in a thriving condition, and prepare them for the pen. Another lot of eleven acres was now added to the first improved and cultivated for several years in succession (through necessity) either in corn or wheat. The production of these lots very soon convinced me of the value of improved land—having reaped for two crops in succession, twenty bushels of wheat for one seeded, from land, which had not within the memory of any man living, produced more than five or six for one. Having now come into possession of other land I was enabled gradually to extend my improvement to the field-system, collecting materials from every resource in my power, which are carried through the stables, farm pen, hog pen, &c.

The farm pen, or shelter, is situated about the centre of my arable land—within forty yards of the barn and stables, where each field corners. It is built of pine slabs on cedar posts put in the ground in the form of an octagan, closed entirely around except a space of fifteen feet on the south side to admit the stock. The yard is graduated to the centre in the form of a shallow basin, which receives the water, and retains it in the vegetable mass, and being too shallow to retard decomposition or putrefaction, yet retains the essence of the manure, so that nothing is lost. In this pound the cattle are penned every night through the year, and during the winter both day and night, except for a short period in the evening when they are turned out to water. I know that in this respect my practice is different from most of our best and most experienced farmers: but from experience I am induced to believe it suits my situation and circumstances better than the more common mode of summer cowpens. The stables are well supplied with a fresh bed of litter every night, and their contents suffered to remain until the mass becomes twelve or eighteen inches thick, when they are cleaned out, and the manure removed immediately to the standing farm pen, spread regularly over the yard, and covered with straw or pine leaves. I always prefer removing the stable manure to the farm pen during a rainy season, or to anticipate a rain, as the essence of the stable manure will be immediately carried down into the bulk below, and mixed with the whole mass. Loads of pine litter from the woods are always carted in previous to carrying in the stable manure, for the purpose of protecting it from the sun and atmosphere.

Under this system the additional labor of hauling the manure made in summer to the field is incurred, but I am satisfied that a much larger space can be manured during the same period, than by the usual mode of summer cow pens. I act upon the principle that labor directed to the raising and applying manures rarely, if ever, fails to remunerate the farmer—one acre of good land being, in my estimation, worth ten, or perhaps twenty, of such as is really poor. This farm pen is cleared of its contents twice a year, in December and April. The manure accumulated from the last of April to December, is then carried to the field intended for corn, deposited in heaps according to the strength of the land, and is covered with common earth, if it is to remain for even a few days before being turned in the land. The manure is thus protected from the sun and atmosphere, and a portion of that which would have escaped, imbibed and retained by the cover of earth, which becomes the more readily mixed with the soil to assist in the process of vegetation. A brisk boy of fourteen or fifteen years old will cover the heaps of manure as fast as a good team of oxen and three horse carts can carry it to the field—say a distance of 700 yards. The manure made during winter is all carried out and ploughed in, as before observed, for the corn crop in the spring, and the only litter used in the farm pen up to this period, consists of straw and pine leaves. Immediately after carrying out the manure in spring, we commence carting in corn stalks, which is continued until they are all used. This mode of using the corn stalks is preferred, because they are not so soon converted into manure as straw, or litter from the woods, and they have a longer period to remain in the farm pen through summer.

All the manure made is applied to land previously marled—a very fine bed of which I have near the centre of my arable land. My marl is that which I think is generally termed yellow, being a decomposed mass of various kinds of shells tinged with clay. No sand is discovered in it. I have applied only 200 bushels to the acre, and believe from several experiments made on a small scale, that quantity sufficient for my land. There are several indications of marl in my neighborhood—and a deposite has recently been discovered of very good quality. I have but little doubt that many deposites of this valuable manure are yet to be discovered, and that our worn-out and neglected country is destined to be brought to a state of gradual improvement.

On my friend Col. J. S. Stubblefield's farm, on Chickahomony, there is found a curious deposite of muscle shells, extending on the bank of the river about one hundred and fifty yards on a level with the flat land, and covering a breadth of from thirty to forty yards. These shells are found on the surface, and extend to the depth of from three to four feet, imbedded in rich black mould. This deposite contains a considerable portion of carbonate of lime, and has been used extensively by Col. S. who is an industrious and enterprising farmer. In this deposite of shells are found a number of human bones of all sizes, from the smallest infant to the full grown man, interred in pits of various size, and circular form; and in each pit are found intermingled, human bones of every size. Standing in one place I counted fifty of these hollows, from each of which had been taken the remains of human beings who inhabited this country before the present race of whites. These remains differ in several particulars from the Indian burying grounds heretofore discovered among us. Might they not furnish curious matter of speculation to the antiquarian? It is time I should bring this desultory communication to a close.

JAMES H. CHRISTIAN.

From the New York Farmer.

DRY ASHES DESTROY LICE ON FOWLS.

When confined, or when simply roosting, in an inclosed house, hens are apt to become infested with lice, in the warmer months. Dry wood ashes, put on the ground where they dust themselves, will, says a farmer, who has given much attention to poultry, very soon entirely free them.

From the last London edition of the "Complete Grazier."

ON THE BREEDING, REARING, AND FATTENING OF SHEEP.

Introductory and comparative view of the different breeds of British sheep.

Among the various animals given by the benevolent hand of Providence for the benefit of mankind, there is none, perhaps, of greater utility than the sheep; which not only supplies us with food and clothing, but also affords constant employment to numerous indigent families, in the various branches of the woollen manufacture; and thus contributes, in no small proportion, to the productive labor, the commercial prosperity, and the opulence of this highly-favored island.

In a wild, or natural state, the sheep is a vigorous animal, lively, and capable of supporting fatigue; when domesticated, indeed, it loses much of these properties, but amply compensates for the absence of them by the superior advantages arising from the rearing of this sort of stock. In fact, on most soils, sheep constitute a material part of a farmer's live stock and profits; and as particular attention has, of late years, been bestowed on the improvement of the respective breeds, we shall first present the reader with an introductory view of them; which will, we trust, convey an adequate idea of the different varieties, together with their specific characters, and the peculiar advantages they respectively possess. The general management of these animals will afterwards form a subject of discussion.

Naturalists maintain that all the varieties of different animals, of the same species, have been derived from one parent stock; and, arguing upon this hypothesis, the origin of our native breeds of sheep has been deduced, by some from the *moufflon* of Corsica, and by others from the *argali* of Siberia, both of which still exist wild in the mountains of those countries. The moufflon is, however, mentioned by very ancient authors as a distinct animal, and, indeed, it appears to partake more of the nature of the goat; but the argali, which is spread throughout Asiatic Russia, and many parts of Persia, has much of the appearance, and many of the habits, of the common sheep. Whatever degree of credit may be attached to this conjecture, it is certain that sheep were found in a domestic state in England at the earliest period of which we have an account; it is also probable, that they were then of one species only—the small horned kind; and there can be little doubt, that the various breeds in existence at the present day, have gradually arisen through the progress of cultivation, and experiments in crossing, as well as from those differences, which will naturally arise, when they are long confined to soils of opposite quality. It might prove an object of curious research, to trace the improvements that have been made in this important branch of rural economy; but, this treatise being intended solely for the use of men of business, our inquiries are necessarily confined to the actual breeds that compose the present stock of the country, of which the following are the chief.

I. The *Heath*, *Linton*, *Short*, or *Forest Sheep*, are names indiscriminately given to the several varieties of the same breed, which is found in the north-western counties of England, and thence forward to the western highlands of Scotland.

The specific characters of this race are, large spiral horns; faces black or mottled, and legs black; eyes wild; carcass short and firm; wool long, open, coarse and shaggy; fleece averaging about three pounds and a half at four years and a half. They are of a hardy constitution, admirably calculated for elevated, heathy, and exposed districts; and, judging from this aptitude to support the hardships of constant exposure in a wild pasturage country, as well as from the form of the horns, which is characteristic of the animal in its unimproved state, it may be not improbably inferred, that they are directly descended from the parent stock of the kingdom. The true black-faced breed, is said to be distinguished by a lock of white wool on the forehead, termed the snow-lock.

In moorland tracts, where the pasturage consists rather of heather than of green herbage, these sheep have been found more valuable than some which, in more favored situations, might be considered superior; and although they have been superseded in some instances, yet they still maintain their ground on the bleak hills of the north, many of which, indeed, would be wholly unproductive to the farmer under any other stock: their flesh is highly flavored; and when fattened on the lowland pastures, they make excellent mutton. There is another moorland breed, of an unmixed race, existing on the Yorkshire wolds, which differs from the former, in having the face and legs white, with a thin flat carcass; but in point of hardiness of constitution, and the characteristic distinction of large horns, it is nearly similar. Both range over the heathy mountains in the summer, without any attending shepherd; and, on the approach of winter, they are brought nearer to the enclosed grounds, that hay may be given to them during deep snows, and also that they may be prepared for the severity of the season, by being salved: an operation which will be hereafter more particularly described.

The other *horned breeds* of English sheep are—

II. The *Exmoor* and the *Dartmoor*, which derive their names from the districts in the northern and western parts of Devonshire, where they are chiefly found. They are long-woolled, with white legs and faces, and are delicately formed about the head and neck; they make very finely flavored mutton; and arrive, when fatted, at two and a half to three years old, to fourteen and sixteen pounds weight per quarter.

The country in which they are reared, is generally over-charged with water, after the autumnal rains, yet this breed sustains the chill of the wet ground even in the infant state, without becoming subject to the rot, which has proved fatal to some other species that have been attempted to be introduced, and even to crosses. Their summer pasture is scanty, and their winter food consists chiefly in what they can pick up, in ranging over extensive tracts of pasturage, with the assistance, in the severity of extremely bad weather, of a little indifferent hay, made from the coarse herbage of the moors; and perhaps occasionally with a small supply of turnips, which are sometimes cultivated, but which, from the wetness of the land, they are often prevented from resorting to when most wanted. From this superior hardiness of constitution, and more especially from their power of resisting wet, which is generally so injurious to sheep, nature has evidently adapted them to the soil; it is not, therefore, to be much wondered at, that the attempts made to improve them by crosses with more tender breeds, have not been attended with all the success that was expected. A cross with the old Leicester sheep has, indeed, increased the weight to twenty-four pounds per quarter; and another, with the Spanish merinos, has improved the quality of the wool; but the foot-rot and the scour have in both instances made great ravages; and until some effectual system of drainage be adopted, by which the pastures may be rendered dry, and shelter be provided by enclosures, the most rational hope of improvement must rest upon increased attention to the native race.*

* See the Agricultural Survey of Devonshire, p. 338.

III. The *Norfolk Breed* is indigenous in the counties of Norfolk and Suffolk. The horns are large and spiral; bodies long; loins narrow, with a high back and thin chine; the legs long, black, or gray; of a roving, wild disposition, and not easily confined within any but strong enclosures. The wool of the original breed was short, the fleece weighing from two to two and a half pounds; but within the last twenty years, in consequence of crosses and new modes of feeding, the weight has been increased full a pound, and the greater part is now used for combing purposes.* The carcass has been proportionably increased; and though the mutton has not been thereby improved, it yet is well flavored, and of a fine grain, but only fit for consumption in cold weather.

The agile form of these sheep, enabling them to move over a great space of ground with little labor, was of vast advantage to the old Norfolk farmers, many of whom were possessed of large tracts of heath-land, which they had no means of bringing into cultivation, except by the assistance of the fold. Mr. Marshall characterizes them, in his account of the Norfolk husbandry, as being singularly well adapted to the soil and system of management prevalent in that country: thriving upon heath and barren sheep-walks, where nine-tenths of the breeds in the kingdom would starve; standing the fold perfectly well, yet fatting freely at two years old, and bearing the drift to distant markets with comparative ease. Mr. Kent has been equally warm in their praise in his survey of the same county; yet notwithstanding these strong testimonials in their favor, they have long been giving way to the more fashionable Southdown breed, which has now taken possession of nearly all, except the most barren and sandy districts of the county.†

IV. The *Wiltshire Breed* are distinguished by large spiral horns bending downwards, close to the head; they are perfectly white in their faces and legs; have long Roman noses, with large open nostrils; are wide and heavy in their hind quarters, and light in the fore-quarter and offal, but with little or no wool on their bellies. The quality of the fleece is that of clothing wool of moderate fineness, averaging nearly three pounds in weight; and the carcasses of the wethers, when fat, usually weigh from 70 lbs. to 90 lbs.: the mutton good: they sometimes, however, reach much higher, and may be considered as our largest breed of fine-woolled sheep.

The county of Wilts, being in great part composed of downland, the same necessity exists there, as upon other light soils, of maintaining large flocks of hardy constitutioned sheep for the purpose of folding; to which the old stock of the country was well adapted. But the improvements in the modern system of agriculture, by the introduction of green crops instead of fallows upon light land, having enabled the farmers to supply their flocks with better winter food than the bare pastures on which they were previously kept, the

* Evidence before a Committee of the House of Lords on the wool trade, in 1828. Printed report, p. 129.

† Agricultural Survey of Norfolk, by the Secretary to the Board; Kent's ditto; and Evidence of Mr. Fison before a Committee of the House of Lords, on the British wool trade, 1828, p. 194.

size of the present race has been increased, and the form has been improved by crossing. It is, however, said, that they have become less hardy, and worse nurses; and, in particular, so very nice in their food, that they will starve on the same kind of land where the former sort of smaller and more compact sheep lived well. Another serious consequence of the change is also said to have been produced by this delicacy of appetite—that by rejecting the feed of the downs, on which the chief dependence of the flock master rests, the herbage has gradually grown coarser; which evil has been further increased by the consequence of shortening the stock previously kept; it being a well known fact, that, to a certain extent, the closer the downs are fed, the more sheep they will support.* But it is more probable that the greatest injury done to the downs has been occasioned by the system, pursued during the high prices of corn, of breaking them up, and after exhausting them by repeated cropping, then laying them down with artificial grasses which soon wear out, and coarse natural grasses then take possession of the land, instead of the finer sward with which it had been previously covered.

It has been also found that the quality of the wool has been injured by the new system of feeding; and in this county, as well as in Norfolk, the native breed has been nearly superseded by that of the Southdowns.

V. The *Dorset Breed* have small horns with white faces and legs: the wool of the pure breed is of an intermediate kind, between long and short, and of middling fineness, weighing from three and a half to five pounds per fleece; and the carcass averaging eighteen pounds per quarter, of excellent mutton. But great numbers of Southdown sheep are bred in the county, and in many instances the blacks have been intermixed, and the character of the original stock proportionably altered. They are a hardy race, being chiefly bred on open downs, and inured to the fold; but their principal value consists in the peculiar forwardness of the ewes, which take the ram at a much earlier period than any other species, and are therefore much sought for, and command high prices for the purpose of producing house-lamb for winter consumption.

The Dorset sheep are chiefly to be found in the county from which they take their name, and in the neighboring borders of Devonshire; but a variety of the same breed occurs in *Dean Forest*, and on the *Mendip Hills*—a small compact animal, that will thrive on the poorest soil and fatten on such land as will scarcely keep other sorts alive. Pasturage ever so dry and exposed will feed this kind: they are very hardy; their wool fine; and the mutton is also excellent for the table, being full of gravy and of a rich flavor.† The Mendip Breed resembles, in many points, the merinos; and there is a tradition that the original stock of the Spanish fine-woolled sheep was obtained either from those hills or from those of Cotswold, in Gloucestershire; but the breed now prevailing in the latter district bears no likeness to them.

The *Polled Sheep* may be divided into two classes—the *long*, and the *short-woolled*—the peculiar merits of which have for many years formed a subject of discussion among agriculturists. Each has valuable properties, and efforts have been made to blend them, by crosses, but hitherto without complete success: nature seems to have intended them for different soils, and the short-woolled breeds, which thrive upon the bleakest hills, degenerate when removed into rich pastures, which are alone capable of maintaining the long-woolled species.

VI. The *Leicester* sheep take the lead among the *long-woolled kind;* and of these there are three nearly distinct species:—

1. The *Forest Sheep*, which, though not confined to the open district of Charnwood Forest, were probably the common field stock and original breed of the county. They are mostly polled, though some have small horns; are generally white, but sometimes gray-faced, with legs of the same color; are covered with coarse combing wool; and are altogether an inferior race.

2. The *Old Leicester*, which are probably descended either from the still more ancient stock of Charnwood, improved by better feeding, and by crosses with rams from the rich pastures of Lincolnshire; or from a large-boned, coarse-woolled breed, long common to the midland counties. They are large, heavy, flat-sided, strong in the bone, and somewhat coarse in the offal and pelt; but full of wool of a combing quality. They are well adapted for the rich, deep, feeding soils, upon which weight of mutton and of wool are more material objects for profit than fineness of quality; and, on such lands, the rams are commonly brought to weigh forty pounds the quarter, with a fleece of twelve to fourteen pounds.

3. The *New Leicester*, or *Dishley Breed* are an improved kind of the old species. Their forms are handsome; color white. Their heads are clean and small, their necks short, and their breasts full; their bodies are round, with broad, straight backs, but the bellies rather light, or tucked up; their legs and the whole bone are fine, and particularly small in proportion to their size; their pelts thin, and the wool long and fine of its kind, generally averaging seven pounds to the fleece. They are of a quiet disposition, fatten early and kindly, and are capable of being brought to a great weight, on a smaller proportion of food than other breeds of the same size, the fat wethers generally weighing (when shear-hogs) twenty-five pounds per quarter, and the ewes twenty-two pounds: the flesh is fine grained and well flavored, but too fat to please most palates.

The final improvement of this breed is unquestionably due to the late Mr. Bakewell; but there are various opinions respecting its origin. Mr. Marshall attributes it to one Joseph Allom, of Clifton, in Leicestershire, who, from being a plough-boy, raised himself by industry to the situation of an eminent farmer, and was the first who distinguished himself, in the midland district, by the possession of a superior breed of sheep. He was known to purchase his ewes at a distance, and it has since been ascertained that he chiefly obtained them in the Melton quarter of the county; but, in whatever manner he raised his breed, it appears certain that it was in high estimation before Mr. Bakewell's time, as it was customary for the most careful breeders to resort to Clifton for

* Agricultural Survey of Wilts, p. 142.

† See the Agricultural Survey of Somersetshire, 3d edit. p. 145.

ram-lambs, for which they gave the then extraordinary price of two and three guineas each: it has, therefore, been not improperly conjectured, by Mr. Marshall, that through the means of Mr. Allom's stock, the breed had passed the first stage of improvement before Mr. Bakewell's day.*

Another author† acquaints us—upon the authority of a gentleman long resident in the county—that about the year 1747 there was a succession of bad seasons, which occasioned a great rot in the sheep upon the clay-lands, that in a short space swept away whole flocks. Some of the small farmers were ruined; but the more opulent and enterprising resorted to the high grounds near Fridaythorpe, in Yorkshire, where they purchased some small neat sheep, which, crossed with the few that remained in their own fields, produced some very useful animals. As the numbers bred for a long time afterwards were not equal to the demand, they sent year after year to the same market: jobbers were established, who employed themselves in purchasing sheep on the Yorkshire wolds, for the use of the Leicestershire graziers; and, it is said, that Mr. Bakewell engaged these men not to offer their sheep to public sale till he had seen them, and had taken such as suited him. From these droves, or from the flocks so bred in his own neighborhood, and probably from a cross with the Lincolnshire, he bred his first short-legged, square-framed sheep, which were so well received that he went on breeding from his own stock, or crossing with any others that he judged most likely to attain the perfection at which he aimed; by which means, and partly, as it has been thought, by a cross with the Durham sheep, he by slow degrees produced the celebrated breed since distinguished by the name of the farm on which he resided. To him, therefore, may be justly conceded the merit of having effected this valuable improvement; but he has left many able disciples, who have followed closely in his steps, and have even so improved upon his system, that not only Leicestershire, but many of the neighboring counties, may now boast of possessing the breed in the highest perfection.

Many good judges are, however, of opinion, that the endeavors to improve the old breed have been carried too far, and that the introduction of the Dishley stock has reduced the quantity of mutton and wool in a much greater proportion of value, than it has improved the quality. It is admitted, that much good was effected by the early crosses, and that the New Leicesters feed quicker, and come sooner to market than the old; but they are deficient in inside fat, and are said to carry their flesh more upon the loin than in the leg; which are both serious faults in the eye of the butcher. It is also alleged, that too much value has been placed on fineness of bone, and that, in attaining that object, the constitution of the animal has been sacrificed; even, in many instances, to the destruction of the generative power in the ram.

VII. The *Lincolnshire Breed* so nearly resemble the old Leicester, that they require but little further description. They have white faces and legs, the bones large, and the carcass coarse; the back long and hollow, with flat ribs, but good loins, and a deep belly; forward loose shoulders, a heavy head, with a large neck, and sinking dewlap; the hind-quarter broad, the legs standing wide apart, and a large dock. The pelt is particularly thick, and the fleece consists of very long combing wool, of a rather coarse quality, but weighing generally from twelve to fourteen pounds on the wethers, and from eight to ten pounds on the ewes. The flesh is open-grained, and inferior to the mutton of the New Leicester, and particularly to that of the small, short-woolled breeds; it is besides subject to be yellow, which is a great defect at market, but it frequently reaches the weight of thirty-five pounds per quarter; and fat wethers generally average twenty-five.* This description, however, applies rather to the old breed of Lincolns, as well as of Leicesters, than to the sheep now commonly ranked under those denominations; for, owing to a judicious intermixture, not carried too far, of the Dishley blood, many of their imperfections have been rectified, while they still retain the valuable properties, so essential on rich soils, of great weight of fleece and carcass, and have further acquired some of the distinguishing marks of the improved breed, in the increased cleanness of the head, straightness of the back, and general symmetry.

VIII. The *Teeswater Breed*, another variety of the old long-woolled species, was formerly the stock of the northern part of the Vale of York, and of Cleveland; but it has, of late years, undergone so great a change, by crosses with Dishley rams, and their descendants, which were introduced into the north, by Messrs. Culley, about the year 1766, that the original race is now but rarely to be met with.

In their pure state, the Teeswater sheep are very large, coarse-boned, slow-feeders, and their wool is dry and harsh; but they arrive at greater weight than any other breed in the kingdom; the three year old wethers reaching to upwards of thirty pounds per quarter,† and producing a fleece of about eleven pounds. The ewes are singularly productive of lambs, twins being not only common, but three, and even four, being sometimes produced at a birth.

A variety of this race, which formerly occupied the lower district of Northumberland, were called *Mugs*, probably, as the surveyors of that county suggest, "from their faces being covered with a muff of wool, close to their eyes:"‡ but they have

† Mr. Pitt, of Wolverhampton. Agricultural Survey of Leicestershire, p. 249.

* Agricultural Survey of Lincolnshire, 2d edit. p. 403.

† A four shear sheep of this kind, bred by Mr. Thomas Hutchinson, of Sockburn, and killed at Darlington, in December, 1777, weighed 62 pounds per quarter; and another, belonging to Mr. Dinsdale, of Newsham, weighed 54 pounds. A wether, rising three years old, bred by Mr. Powley, of Thorndon-Stavard, and killed in January, 1799, weighed 59 pounds per quarter; and a lamb, five months old, bred by Mr. Henry Hutchinson, weighed 22 pounds per quarter. See Agricultural Survey of Durham, p. 248; and Agricultural Survey of Yorkshire, North Riding, p. 260.

‡ Agricultural Survey of Northumberland, by Messrs. J. Bailey, and G. Cullep, 3d edit. p. 150.

given way to the Dishley breed, or have been so improved by crosses, as to retain but little of their original appearance.

The value of this species of stock may be in a great degree estimated by its aptitude to increase in flesh at an early age, and when no particular means of fatting are used; of which the following account of four, fed by Mr. Mason, of Chilton, affords a fair specimen:—

Lambs. Wt. Aug. 15, 1803.	Shearlings. Wt. 4 Oct. 1804.	Gain	Two Shear. Gained to 15 Oct. 1805.
lbs.	lbs.	lbs.	lbs.
92	202	110	34
82	193	111	38
87	216	129	32
91	199	108	28
352	810	458	132
88	202½	114½	33

Thus, the weight gained from five months to one year and seven months old, is 114½ lbs., or at the rate of 1 lb. 15 oz. per week; but from that age to two years and seven months old, the gain in weight is only 33 lbs., or 10 oz. per week.*

IX. The *Romney Marsh* sheep have existed immemorially on that rich tract of grazing land, on the southern coast of the counties of Kent and Sussex, from which they take their name. In their pure state, they are distinguished by white faces, a considerable thickness and length of head, and a broad forehead, with a tuft of wool upon it; a long and thin neck, and flat-sided carcass. They are wide on the loin, but have a sharp chine, and the breast is narrow, and not deep; the belly large; a good cleft; the thigh full and broad, carrying the chief weight in the hind quarter; the tail thick, long, and coarse; the legs thick, with large feet, the muscle coarse, and the bone large. The wool is a good combing quality, the fleece of fattening wethers weighing from eight to nine pounds; the mutton is equal to that of any of the large polled breeds, and their proof being good, they are favorites with the butchers. When fat, the wethers usually average from ten to twelve stone each, and the ewes from nine to eleven.† They are very hardy; are bred with little care, on wet and exposed land, requiring, after the first year, when they are wintered on the uplands, no other food in the severest situation, than occasionally a little hay, in addition to their pasture; and are fattened entirely on grass.

Within these few years, the fashionable Leicester breed has been introduced into Romney Marsh, and the cross has, no doubt, improved the form of the native sheep; but its effect, in the opinion of a very competent judge,‡ "has evidently been that of reducing the size of the animals, and making the wool coarser, but giving them a better disposition to fatten." The rage for Leicester sheep seems, however, to have subsided among the marsh graziers, and the ram breeders are now anxious to make it appear, that their stock is unmixed with the Dishley blood; though, in truth, there are but few, if any, flocks without at least a remote dash of it. Besides the diminution of weight of carcass, and the deterioration of the fleece, the Leicester breed has been found too tender for the cold and open pastures of the marsh. The breeders complain that they suffer great losses from the delicacy of the lambs, and the ewes are found neither to produce so well, nor to be such good nurses as those of the original race; but the improved disposition to fatten must be allowed to be of great advantage. Mr. Price, who has been already quoted, informs us, "that, at no very distant period, the wethers seldom reached market till three years old, but now two years old wethers, and sometimes even yearlings, are sold to the butchers;" and he adds, as his opinion, "that this variety may be made the most valuable in the kingdom for rich pastures, as producing most meat at the least expense, and thus afford the grazier the greatest profit."

X. The *Devonshire* polled sheep form two distinct varieties of the same breed:—

1. The *South Devon* or *dim-faced Nott*, with brown face and legs; a crooked backed, flat-sided, coarsely boned and woolled animal, carrying a fleece of ten pounds average weight, and averaging 22 lbs. per quarter of good mutton, at thirty months old.

2. The *Bampton Nott*, with white face and legs, though in other respects nearly resembling the former in appearance; but the wethers will, at twenty months old, average as much weight of carcass as the others at thirty, and, if kept on for another year, will reach, when fat, as much as 28 lbs. per quarter. They are not, however, equally productive of wool; for, at the first period, they only yield about 6½ lbs., and at the latter, 8 lbs.

Considerable improvement has been effected in the form of these sheep, as well as in most other of the long-woolled breeds, by crosses with the *new* Leicesters, and a greater aptitude has been acquired to fatten at an earlier period; but while many of their defects have been thus cured, the same complaints are made, as in the other instances already noticed, of increased tenderness in the lambs, which are found to require extraordinary care and nursing, yet often perish through the severity of the weather: also of a very material diminution in the weight both of the fleece and carcass; the former being reduced from ten pounds to eight, and the latter from twenty-two pounds to nineteen pounds per quarter. They are likewise bare of wool upon the belly, which occasions great injury to animals constantly lying out, and much exposed to wet; none of which disadvantages have attended a cross with the *old* Leicester, which has, on the contrary, increased the weight of flesh, as well as the disposition to fatten.*

Another variety of long-woolled sheep is found on the *Cotswold Hills*, to which most of the remarks already made on the Devon breeds will equally apply.

The chief of the *short-woolled* breeds are—

XI. The *Southdown*, of which the specific characters are—faces and legs gray; bones fine; head clean; neck long and small; low before; shoulder wide; light in the fore quarter; sides and chest deep; loin broad; back bone rather too high; thigh full, and twist good; wool very fine and short, (the staple being from two to three inches in length,) weighing an average of three pounds and a half per fleece, when killed at two years old. Flesh fine grained, and of excellent flavor; quick feeders; constitution hardy and vigorous. They are round in the general appearance of the barrel; and, from standing wide on their hind legs, and being shut well in the twist, the leg of down mutton is remarkably round and short, not only cutting handsomely for the table, but weighing heavier than common in proportion to the fore quarter—which are material advantages to the butcher, as they command a ready sale, at an advance of a penny per pound over the other joints. Fat wethers usually average about 18 lbs. per quarter; but this has been, in many instances, increased by late attempts to improve the size of the carcass. Whether these have been judicious, time alone can determine; but it does appear from the evidence of some of the persons examined before a select committee of the House of Lords, appointed in 1828, to take into consideration the state of the British wool trade, that they have injured the quality of the fleece.* This has, indeed, been denied by the breeders; but in all other instances, it has been uniformly found that efforts to increase the flesh have been attended with similar effects. In the present state of the wool trade, this may, however, be of less consequence than it might have been some years ago, for it appears from all the concurrent evidence produced before that committee, that the British carding, or short clothing wools, have been entirely superseded in our manufactories, by the German and other foreign kinds. But too great an increase of carcass may also injure the quality of the mutton, which is now of the very finest kind.

These sheep have been bred for ages past on the chalky soils of the Southdowns, in Sussex, and on such short pasture, and in such exposed situations, they are perhaps the most valuable breed in the kingdom; but they are spreading fast not only into similar districts, but into counties better calculated for long-woolled and larger sheep. That the breed will, on those rich soils, degenerate in the superior properties of their flesh and wool, there can be little doubt; but it will still be matter of calculation, whether that disadvantage may not be more than balanced by superior weight. On their native downs, it will probably be found better to preserve them as near to their original size as possible: for, if too large for the constitution of the soil, it will be difficult, if not impossible, to maintain the increase of weight; or, if maintained, it probably will be with some loss either of the hardiness or activity requisite to their thriving on the land for which they are most appropriate; or with detriment to the qualities of the flesh and wool; and thus an apparent advantage may lead to serious future injury.

XII. The *Cannock Heath* sheep are bred upon an extensive waste, so named, in Staffordshire; they are very generally gray faced; without horns; bear fine wool; and from many points of similitude between them and the Southdown breed, it has been thought that they were originally derived from the same stock. The bone, however, is coarser; nor do they possess the same beauty and compactness as the downs; but these defects probably arise from inattention on the part of the former breeders, which the present flock-masters are making efforts to rectify; and, to counterbalance them, the carcass is heavier, and the mutton equally good.

XIII. The *Ryeland Breed* is so called from a district in the neighborhood of Ross in Herefordshire. They are small, white faced, and hornless; the wool growing close to their eyes; are light in the bone; have small, clean legs; and, when proper attention has been paid to the breeding stock, possess great compactness and symmetry. The ewes weigh from nine to twelve and fourteen pounds, and the wethers from twelve to sixteen pounds per quarter, when fatted, at three to four years old, and their flesh is equal to any mutton in the kingdom. The fleece does not average more than two pounds; but the quality of the wool is unrivalled by that of any of our native stock. They are patient of hunger, and no breed is supposed capable of subsisting on a smaller quantity of food; they are, therefore, adapted to the pasturage of down land; but they require a fine herbage, and are so tender as to require shelter in the winter; and particularly at the time of lambing. They are not, as many persons imagine, wholly a mountain breed, being kept in the vale lands as well as on the hills, and are often fatted on the same soil with the Hereford oxen.

A cross has been made between this breed and the Spanish sheep, the produce of which are termed *Merino Ryelands*, and the wool *Anglo Merino*. The first stage of the cross materially detracts from the beauty of the Ryeland's form; but the fleece is much improved both in weight and quality, and the carcass is increased, while the flavor of the mutton remains uninjured. It has been affirmed, that the characteristic properties of the Merino Ryelands correspond with those of the Spanish race as far as the fourth generation, and that the wool is nearly of equal quality to that of the pure merino. Great exertions were made by the late Dr. Parry, of Bath, and other spirited wool-growers to introduce them to general notice; but it appears, from the evidence produced before the Committee of the House of Lords, already mentioned, that this new breed has declined; and that, either from the general depreciation in the value of short wool, or, as some allege, from deterioration of the quality of this species, the anglo wool is now nearly unsaleable, though it still commands a higher price, when sold, than the finest pure British.*

* See the Evidence in the Printed Report, of Mr. C. Bull, of Lewes, Woolstapler; Mr. Sutcliffe, of Huddersfield, ditto; Mr. Brooke, of Honley, near Huddersfield, Cloth-manufacturer; Mr. G. Goodman, of Leeds, Wool-factor; and of Mr. Sheppard, of London, Blackwell-Hall factor, Chairman of the London Committee of the Woollen Trade.

* See the evidence of Mr. Cunnington, of Upavon, Wilts, Woolstapler; Mr. W. Ireland, of London, and Chalford, in Gloucestershire, Manufacturer; and of Mr. G. Webb Hall, of Sneed Park, Gloucestershire, Farmer.

Another cross has also been attempted between the pure Ryeland and the new Leicester breeds; but although the weight of the carcass has been thereby much increased, yet it can only be supported on land of a much richer kind than that on which the native sheep are usually fed, and it is probable, that if persevered in, on such soils, it would materially injure the mutton, while its immediate effect was certainly detrimental to the wool.*

In some of the neighboring counties to Herefordshire, both in England and Wales, there is a breed of sheep very much resembling the Ryelands, known as the *Shropshire morf.* They bear wool of a fine quality; generally have white faces and legs, though sometimes a little freckled; are light in the bone, and have small clean limbs. There are two species, which, from inattention to the breeds, are often blended. The one polled, the other having small, light, crooked horns—a still smaller variety, bred on the mountains, and in high estimation for the table; but which is generally known under the common denomination of *Welch.*

XIV. The *Cheviot Sheep* were originally bred upon the hilly districts in the north-west part of Northumberland, but have since spread over many of the mountainous tracts in the neighboring counties, and have even nearly superseded the horned breed of black-faced sheep in some parts of the Highlands of Scotland.† They are hornless, and their faces and legs are in general white, though formerly the prevailing color was black; some, however, still retain a portion of black about the nose; and others have the face slightly tinged with yellow. The best breeds have an open countenance, with lively prominent eyes; long bodies, and fine, clean, small-boned limbs, but wanting depth in the breast, and on the chine. They are seldom slaughtered until they have attained the age of three to four and a half years, when the fat wethers will average from 16 lbs. to 22 lbs. per quarter, and in some instances still higher, fattening kindly, and producing mutton of excellent quality. Formerly the average was much lower, not exceeding 12 lbs. to 18 lbs., and they were kept longer before they were brought to market; but great improvements have been made in this stock within the last twenty years. The weight of the fleece has also been increased in some of the best flocks from $2\frac{1}{2}$ to $3\frac{1}{2}$, to as much as 4 lbs. to $4\frac{1}{4}$ lbs.;‡ but the wool is inferior to that of most other of the short-woolled polled breeds, and appears to have been injured by some late attempts to improve the carcass.§ It is, also, further deteriorated in the eye of the woolstapler, by the practice of smearing, or *salving*, as it is termed, of the flocks pastured on the most elevated hills, with a mixture of oil or butter with tar and turpentine, in order to protect them against the inclemency of winter: this custom, however, is now nearly disused in the lowlands, though in many places it is yet thought advantageous to the fleece.*

The sheep known as the *Herdwick Breed,* though smaller than the Cheviot, and only found in one rocky and mountainous district at the head of the Duddon and Esk rivers, in Cumberland, appear to be only a variety of the same race. The wethers and ewes are all polled: their faces and legs are speckled; but a great portion of white with a few black spots are accounted marks of the purest breed; of which also the hornless are tups; for when these are found with horns, they are considered as descended from a cross with the common black-faced heath species, and their wool is then generally intermixed with *kemps,* or hairs.

They are a hardy breed, well adapted to seek their food amongst the rocks which they inhabit; which are in many places bare, and, where covered, the soil is thin, but the herbage mostly green, though heath is found on the summits. They have no hay in winter, but support themselves in the deepest snows by scratching down to the herbage, and should any part be blown bare, they are sure to discover it. In storms they gather together, and keep stirring about, by which means they tread down the snow, keep above it, and are rarely overblown. The lambs are protected by nature, being well covered with wool when they are dropped.

The ewes are kept as long as they will breed, which is often until ten and even fifteen years of age: the wethers go off at the same age as the old Cheviots. Both ewes and wethers are sold from the mountains, and killed without being put on any better pasture, yet are sufficiently fat, and the wethers will weigh about 10 lbs. to 12 lbs. a quarter: the ewes from 6 lbs. to 8 lbs. From being fed on heath and mountain plants, the flesh acquires a peculiarly fine flavor, when these are in blossom, from July till September, and is then esteemed a great delicacy; but, when out of season, the mutton is dry and indifferent.

The mountains on which these sheep are bred are the property of Lord Muncaster, who is also proprietor of the flocks that depasture them; and having, from time immemorial, been farmed out together to herds, it is thought that, from this circumstance, the farms have obtained the name of *Herdwicks,* or the district of the herds; from which the sheep have also received their title. They are chiefly in the hands of one family, of the name of Tyson, which is said to have been settled in that sequestered spot above four hundred years.†

Another variety, termed the *Dun-faced breed,* is found in the exposed northern districts of this island. The faces of the sheep are of a dun, or tawny color: the animals are smaller in size; have short tails; and are not so hardy as the preceding sort. The wool is variously streaked with black, red, brown, or dun, and partly of a fine texture, weighing about a pound and a half per fleece,

* 12 lbs. of butter mixed with 4 lbs. of tar, are used for the salving of twenty-four sheep: the expense about sixpence each.

† Agricultural Survey of Cumberland, Chap. XIII, Sect. 11.

when killed at four years and a half. Flesh finely grained, and of excellent flavor.

The *Shetland Breed,* a nearly similar race, derives its name from the islands on the north coast of Scotland, where these sheep are reared. The wool is very fine and soft, fit for the finest manufactures: the fleece weighs upon an average from one to three pounds. The Shetland sheep are very hardy, but too wild to be confined. There are two varieties of this breed; the *first* of which has very coarse wool above, and fine wool below, being supplied with long hairs termed *fors* and *scudda,* which protect the animals from the intense cold of winter; the *second* variety has soft, cottony fleeces, and is less hardy than the preceding variety, the wool being short and open: the weight of the wether carcass of either does not average more than 8 lbs. per quarter.

The *Isle of Man* possesses a breed of apparently the same parentage, but partly horned as well as polled: their general color is white, but many are gray, and a few of a peculiar brown color, provincially termed *Laughton.* In the whole breed one distinctive mark is said to appear in a Laughton-colored patch on the back of the neck; and it is somewhat singular that a similar mark has been observed on sheep from the island of Iceland, which are, indeed, said to bear a general resemblance to the Manks breed. It is observed, that sheep of the Laughton color are more tender and slower feeders than the others; but their wool is peculiarly soft, and is held in high estimation for the manufacture of stockings. The mutton of each sort is excellent; but in other respects the breed is little deserving of attention. They are of mean appearance, with high backs and narrow ribs; slow feeders, and long in coming to maturity. Many attemps have been made to improve them by crosses with Leicester, Southdown, pure Merino, and Ryeland Merino rams. These have in some degree succeeded, and in particular the cross between the Southdown and the Manks is said to be little inferior to the male parent; that with the Ryeland Merino having been judiciously made with some of the finest woolled ewes, has greatly improved the fleece; but it is admitted that these half-bred Manks Merinos are not good feeders.*

* Agricultural Survey of the Isle of Man, Chap. XIV. Sect. 11.

QUERIES AND DESULTORY OBSERVATIONS ON MANURING, &c.

To the Editor of the Farmers' Register.

In a late No. of the Register it is said that land originally poor can never be brought to a higher state of fertility unless calcareous manures are used—or to that effect. Now as your reasoning appears to me to be conclusive, as to the fact, it is my wish to test it by an experiment. I have about three acres of land, just cleared, of rather inferior quality. It is pretty well covered with litter, leaves, and coarse grasses, which have sprung up in consequence of the land having been partially cleared for several years. It is my purpose to put the land in tobacco the next year. As I cannot get marl, I intend to use lime, and wish you to be good enough to say in the Register, whether it must be used before grubbing and coultering, or not? whether before or after the trash is removed —and what quantity of slaked lime to the acre will be sufficient to *begin* with? and when to be repeated, &c. &c.*

Would it not be well to urge (through the Register) upon the friends of the enclosing system, the propriety of meeting in convention, through representatives from all the counties below the ridge, in order to prepare and present a joint memorial to the legislature, for amendments of the law of enclosures? The prosperity of our poor old state depends, in my judgement, more upon this measure, than upon any other, or all others—whether they consist of internal improvements by rail roads, canals, turnpikes, improvements of the channels of rivers, locks and dams, or any thing else the wisdom of the legislature may think proper to devise. The plan for enclosing our stock, instead of enclosing our crops, extends its benefits to every individual in the state, and, with peculiar certainty, to the *poor non-land-holder;* whereas, those systems which give facility to our intercourse, apply mainly to the wealthy—having a tendency to make the rich richer. Do not understand me to be an enemy to any system of internal improvement. I only mean to place the one under consideration above all others, as the benefits to arise from it are general.

In a small way I have been a very successful corn raiser; and I have ascribed my success principally, to my planting corn much *thicker* or closer together than my neighbors are in the habit of doing. My rule is, where the land has sufficient strength, under good cultivation, to produce as much as five barrels to the acre—to throw the land into ten feet beds—lay off two rows on a bed, the row next to the bed furrow to be six, and the other four feet wide. The corn is dropped three feet a part, and thinned to two stalks in a place. This gives seven and a half square feet of land to every stalk. This rule applies to the large soft corn of the south. If I plant small flinty corn on similar land, I reduce the number of square feet to six for every stalk. If the land is capable of bringing ten barrels to the acre, I would reduce the number of feet to each stalk nearly one-half: and on the other hand, if compelled to cultivate poorer land in corn, I would increase the number of square feet in similar proportions. I usually run the new ground coulter next to the corn as early as possi-

*Our personal experience of the use of *quick* or *caustic* lime is very limited, and the views which we entertain, as to the manure in that state, are more theoretical than practical. They have been expressed more fully in Chap. 8, of Essay on Calcareous Manures. Newly cleared land would probably receive, without damage, a heavier dressing of quicklime than most other arable soils. Still we should fear to give more than 150 bushels of slaked lime—though three or four times that quantity, if mild, (as in marl,) might be applied to such land, safely and advantageously. In either case, the best time to apply the lime, or other calcareous manure, would be before removing the leaves and litter—which indeed should not be moved at all, if the main object is the improvement of the soil. How far leaving the litter would be opposed to the first crop proposed, tobacco, is a different question.—Ed.

ble, and use the mould-board plough, or not, according to the progress of the weeds and grass in the after cultivation. My opinion is, whenever corn requires ploughing, it requires *deep* ploughing, unless it is when the corn has been planted upon a recently well turned turf—*that*, I think, should never be disturbed by after deep cultivation. Simply keep the land clean by shallow culture.

I have been in the habit of using leaves and straw, and coarse manure, for the corn crop, in the following manner, with great benefit: plough the land in nine feet beds—or rather open deep furrows nine feet apart, in the fall or winter—fill them with straw, leaves, or coarse manure—throw back the earth immediately, and when you have finished, break the land at your leisure—in beds of course—and plant the corn in rows only three feet wide, in the centre of the nine feet bed—that is, eighteen inches from the centre of the rubbish row. You will then have a six and a three feet row to each bed, giving the corn distance according to the supposed strength of the land. In cultivating the crop, the three feet row is simply to be kept clean with the hoe or skimmer, the leaves, &c. to remain undisturbed in the process of cultivation. The six feet row to be ploughed as deep as possible, but not with a mould-board plough if the land is very poor.

When you give directions to plain farmers about improving their lands, it would be well to use the simplest terms, and such as the very ignorant are accustomed to use among themselves. Say for instance, "gray land" with a "red or yellow foundation" may be improved by such and such means—omit the terms "alluvial"—"loam," &c. &c.; and in all other respects adapt your terms to the meanest capacity, if possible. The wise will understand you quite as well, and the ignorant will be delighted, and soon begin to prefer the Register to all other publications. When it is absolutely necessary to use scientific terms, define them, for there are few clod-hoppers who have dictionaries, and many that don't know "how to look for words in them."*

When you allude to *our* now universal practice of top-dressing with *well rotted manure*, you generally use the term "*this novel practice.*" Some think you mean, thereby, to deride the practice. My own experience does not warrant me in saying the improvement is as permanent as the old method of turning in the manure—but I will state a fact in relation to an experiment made by a friend of mine, to which my attention has been repeatedly called. Five years ago last fall, this friend had a lot of ten acres which he was desirous of getting in clover as soon as possible. He thought he had a sufficiency of manure (well rotted farmpen) to make the whole ten acres rich. He commenced hauling, spreading, and ploughing in the manure, at the rate of *forty thirty-bushel loads* to the acre, *upon four acres of the best part of the lot*. After proceeding this far, he discovered that his manure would not hold out, at *that rate*, to complete the lot; he therefore determined to plough the land—sow the wheat, and reserve the balance of the manure for top-dressing. In the succeeding winter he proceeded to complete his work—sowed the land in clover, and top-dressed the remainder of the lot at the rate of *twelve loads* to the acre. The succeeding wheat crop on this part of the lot was equal to the other—the clover crop was better. There has been one wheat crop on the land since, which was equally good throughout—and as far as can be judged by the eye, the lot is now about equal in fertility in all its parts. This experiment has satisfied me as to the permanence of "this novel practice of manuring land."

I will call your attention to one circumstance, which in my judgement, goes, measurably, to the refutation of your idea, "that land originally poor can never be rendered more fertile, or raised above its original fertility without the use of calcareous manure." You have no doubt frequently remarked the *abiding* fertility of an acre or two of land where old settlements had been broken up and the land put in cultivation, while the adjacent lands evinced *original* poverty of soil. This is certainly the case *here*, where we have neither lime, nor marl, nor oyster-shells. Admitting the fact, what is the conclusion? Perhaps you will ascribe it to the caustic quality of the ashes that have been thrown out for fifty years. But you know that ash heaps frequently lie undisturbed for ten or fifteen years; and such is the ignorance respecting

---

*We take this advice in good part, but claim that we have always endeavored to use terms as plain as possible. But while agreeing entirely in this respect with our correspondent, as to proper *ends*, we differ altogether as to the *means* by which to reach them. We think that to render agricultural terms as plain as possible, it is necessary that they should be *correct*—and that if correct terms are substituted by the provincialisms of a particular district, the terms would become plain to that district only by being made obscure to all others. We can assure our correspondent that even the meaning of "gray land" would be unintelligible to half the farming world, and that the term is not known in some counties within ninety miles of Goochland, except to those persons who have heard its use abroad. We differ as to another mean for reaching the end, *plainness*, which we both claim to approve and to seek. Certainly terms purely scientific, or technical, ought to be explained, at least often enough for every attentive reader of the work in which they are used, to learn the definitions. But if such terms as "loam," "alluvial" &c. are meant as requiring to be always defined—or even if scientific terms are to be explained every time they are used, the style of many communications would necessarily be something of the fashion of the account of "The House that Jack built," and the end and meaning would scarcely be sought by any reader among the mass of explanatory accompaniments. In short, the reader who expects every piece to serve as its own dictionary, and who will not ask or seek for explanation of a difficulty, would scarcely profit by any facilities that could be afforded. The next paragraph furnishes an example of the extent to which definitions would be required, if it is necessary to explain that when we spoke of top-dressing wheat as a "novel" practice, we neither meant to deride, nor to oppose it: but on the contrary, consider it as one of the most valuable improvements made known through the Farmers' Register.—Ed.

their value, they are rarely distributed at all by small house-keepers. My conclusion on the subject is this—that those lands about the old settlements having been top-dressed for forty or fifty years, become permanently rich in consequence thereof. This is a very *novel* idea, and perhaps you will think it a very silly one: at any rate, I think it probable that top-dressing will become the universal mode of manuring land.*

Permit me to call your attention to a method of pulverizing fresh ploughed lands by the use of a drag-log, described in a late No. of the Genesee Farmer, by a friend of ours. I have used it for eighteen months, and think that one rubbing is worth a dozen harrowings for the purpose of rendering fresh ploughed land fine and mellow.†

T. W. P.

Goochland, June 10th, 1835.

---

*The well known fact stated above of the permanent fertility exhibited on the sites of old dwelling places on naturally poor land, instead of opposing the opinion referred to by our correspondent, is in truth, one of its strongest supports—and we have often claimed its aid in argument, for that purpose. It is not the "caustic" quality of the ashes which produces the benefit, but the calcareous earth they contain, amounting to perhaps, half their bulk—and to the phosphate of lime, which forms part of the balance. This substance constitutes the most solid part of bones. But independent of this portion of phosphate of lime, and of that in all the bones left near the residence of a family, the calcareous earth alone from the ashes, and other sources, would be amply sufficient to fix the permanent fertility always seen on such spots. The other sources of lime are almost every thing brought to and consumed at the residence of a family: for, every article of food and clothing, as well as fuel, contains some lime—all the offal of crops, &c., and therefore the proportion of lime at and near a dwelling place must be always increasing, because more is brought to it than is carried away.—ED.

†The communication referred to has already been published in this journal, page 751, vol. II.—ED.

ORIGIN AND VALUE OF THE IMPROVED SHORT-HORNED BREED OF CATTLE.

For every portion of the text in this excellent account of the short-horns, we are indebted to the Rev. Henry Berry, than whom there are few more zealous breeders of cattle, while there is no better judge of them.

Whatsoever differences of opinion may prevail respecting the comparative merits of our several breeds of cattle, it must be admitted that the short-horns present themselves to notice under circumstances of peculiar interest. Possessing in an eminent degree a combination of qualities which have generally been considered incompatible, and rendered irresistibly attractive to the eye by their splendid frames, and varied colors, it is not surprising that they have become objects of public curiosity; that they have realized for their breeders enormous sums of money; and that throughout our own island, and in every foreign country where agriculture is attended to, they are in increasing request.

It might tend to throw much light on the science of breeding, could these animals be traced, in the progress of their improvement, to an earlier period than has hitherto been found possible. Of the extent of that improvement, we may, however, form an estimate, by placing together one of the improved, and one of the unimproved race. We should, in such case, discover resemblance just sufficient to support the belief in a very remote alliance, but there all similarity would cease.

From the earliest periods as to which we have any accounts of our breeds of cattle, the counties of Durham and York have been celebrated for their short-horns, but principally, in the first instance, on account of their reputation as extraordinary milkers.* To recite their feats at the pail would be to invite incredulity; but it may be asserted, on the best evidence, that, taken as a breed, they have never, in this particular, been equalled. The cattle so distinguished were always, as now, very different from the improved race.

They were generally of large size, thin skinned, sleek haired, bad handlers, rather delicate in constitution, coarse in the offal, and strikingly defective in the substance of the girth in the fore-quarters. As milkers, they were most excellent, but when put to fatten, as the foregoing description will indicate, were found slow feeders, producing an inferior quality of meat, not marbled or mixed as to fat and lean, and in some cases, the latter was found of a particular dark hue. Such, also, are the unimproved short-horns of the present day, and the distinction cannot be too frequently asserted, because they are, in many cases, considered as specimens of the improved breed, and have actually been resorted to in trials as to the comparative aptitude of animals to fatten—trials which is evident they could not successfully sustain.

A period of more than eighty years has now elapsed since the short-horns on the banks of the river Tees, (hence called the Teeswater breed,) had assumed a very different character to that

---

* Before this, a large and valuable description of cattle had existed on the western coast of the continent of Europe, and extended from Denmark to the confines of France. They were celebrated for the great quantities of milk which they yielded, and some of them exhibited an extraordinary aptitude to fatten. At what particular time they found their way to England, or by whom they were imported, is unknown; but there is a tradition, that, towards the close of the seventeenth century, a bull and some cows were introduced into Holderness.

In external form, there appeard to be very little to recommend them, for they had large shoulders and coarse necks, the sides were flat, and the head was thick; all the coarse parts were bulky and the prime ones were reduced in size, and they were almost the reverse of what the agriculturist would select: they were, however, bulkier than the native breeds, and they were better milkers than the generality of the cattle of that day. They would, by dint of feeding, grow to an enormous size, but they had not the aptitude to fatten, nor the early maturity, to which they have been since indebted for their triumph over every other breed.—*Farmer and Gardener.*

contained in the foregoing description. In color they resemble the improved short-horns, being occasionally red, red and white, and roan, though the last named color was not then so prevalent as now. They possessed a fine mellow skin and flesh, good hair, and light offal, particularly wide carcasses, and fore-quarters of extraordinary depth and capacity. Perhaps no closer modern resemblance can be found to the above description of the Teeswater breed than Mr. Berry's bull presents. His dam was purchased by Mr. B. on account of the very few crosses that intervened between her and some of the best Teeswater cattle, to which he was desirous to go back, on account of the extent to which breeding *in and in* has been carried. When slaughtered, their proof was extraordinary, and many instances are recorded of the wonderful weight of their inside fat.

The remarkable difference which existed between the Teeswater and the old unimproved short-horns, may, with propriety, be ascribed to a spirit of improvement which had sometimes manifested itself among the breeders on the banks of the Tees, whose laudable efforts were well seconded by the very superior land in the vicinity of that river. No reasonable doubts can be entertained that they proceeded on a judicious system of crossing with other breeds, because it was utterly impossible to raise such a stock as the Teeswater from pure short-horn blood. One cross to which they referred was, in all probability, the white wild breed; and it this conjecture be well founded, it will be apparent whence the short-horns derived a color so prevalent among them.

It is also asserted that, about the period in question, Sir William St. Quintin, of Scampston, imported bulls and cows from Holland, which were crossed with the stock of the country. It would tend to little advantage to proceed with conjectures, as to what other breeds were resorted to, if any; this much is certain, that great improvement was soon manifested, and a valuable variety established, as the two following instances will prove.

Mr. Millbank, of Barmingham, one of the leading improvers, bred and slaughtered an ox, which, at five years old, weighed four quarters, one hundred and fifty stones, of fourteen pounds to the stone, producing sixteen stones of tallow; and a cow bred from his stock, slaughtered by Mr. Sharter, of Chilton, at twelve years old, weighed upwards of one hundred and ten stones.

From Mr. Millbank's time, the Teeswater cattle continued to sustain their excellence and celebrity in various hands, until Mr. Charles Colling adopted them, when he manifested a superiority of skill as a breeder, which, in a very brief period, secured him an ample fortune.

Whatever has been the merits of the Teeswater cattle, it is certain Mr. Colling greatly improved them; and though it has been asserted that his success was the result of chance, arising from the possession of an animal, with the merits of which, it is supposed, he was at one period unacquainted, the writer of this article is of opinion that Mr. Colling's success resulted from a deliberate and well considered plan. He found the Teeswater, like all other extravagantly large cattle, frequently of loose make and disproportion. He was sensible, also, of the difficulty of breeding, with any thing like certainty, *large good* animals, and though he has declined on all occasions to throw any light on his views and proceedings, the writer thinks he can detect, in the very outset, and through the progress of his practice, a resolution to reduce the size of this breed, and at the same time, and by that means, to improve its form. This he is supposed to have effected, in the first instance, through the medium of a bull called "*Hubback*," an animal respecting which there has been much controversy, principally touching the purity of his blood, a question now of little importance, because it is admitted on all hands that Mr. Colling adopted another cross, which prevails in a majority of superior short-horns of the present day. It may, notwithstanding, be a matter of interest to state a few particulars respecting this bull.

Without entering on an inquiry by what circumstances Hubback's title to be considered of pure blood is supported or weakened, it may suffice to observe, that it appears probable he possessed on one side the imported blood. The possessor of his dam was a person in indigent circumstances, and grazed his cow in the highways. When afterwards she was removed to good land, near Darlington, she became so fat that she did not again breed; and her son, having the same feeding propensity in a high degree, was useful as a bull during a very short period. The quality of his flesh, hide, and hair, are supposed to have been seldom equalled: and as he was smaller than the Teeswater cattle, he was eminently calculated to forward Mr. Colling's views.

It has been remarked that we have at present no superior horse on the turf, which does not boast the blood of the Godolphin Arabian; so it may be asserted that we have no superior short-horns which do not claim descent nearly, or remotely, from Hubback.*

---

* This is true, because Hubback was the sire of the dam of Mr. Charles Colling's bull, Foljambe, who was the grandsire of Favorite; and there can be no doubt that there has not been for many years any superior short-horn who was not descended from Favorite. Mr. Charles Colling is said to have considered that the bull Foljambe, was the one that did his stock the greatest good; and this is not improbable, as Foljambe was the sire both of the sire and dam of Favorite. Hubback, however, must have been a remarkable good animal; and considering the short time during which he was used as a bull, proved himself a first rate stock getter. The following account of Hubback we had from Mr. Waistell, of Allhill, who, although his name does not appear conspicuously in the "Short Horned Herd Book," deserves much credit for his discrimination here. He used to admire this calf as he rode almost daily by the meadow in which it grazed; and at length he attempted to purchase it from the owner. The price asked, £8, seemed much for a calf not a year old and the reputation of the short-horns not being yet established, the bargain was not struck. Still he longed for the young beast· and happening to meet Mr. Robert Colling near the place, he asked his opinion of the animal. Mr. Colling acknowledged that there were some good points about him; but there was something in his manner of acknowledging this, which induced Mr. Waistell to suspect that Mr. Colling thought somewhat more highly of the calf than his language expressed, and therefore, he hastened the next morning, concluded the bargain, and paid the money. He had scarcely done so before Mr. Robert Colling arrived for the same purpose, and as the two farmers

After the use of this bull, Mr. Charles Colling proceeded with singular success to produce, from time to time, superior animals; and the number of bulls he disposed of by letting was highly encouraging. But the circumstance which brought the improved short-horns into most extensive notice, was, the production of the "Durham ox," an animal which speaks volumes in favor of even a single cross of this blood: for the ox was the produce of a common cow, which had been put to "*Favorite*." At five years old, the Durham ox was sold to Mr. Bulmer, of Harmby, near Bedale, for public exhibition, at the price of £140: this was in February, 1801. He was at that time computed to weigh 168 stones, of 14 lbs., his live weight being 216 stones; and this extraordinary weight did not arise from his superior size, but from the excessive ripeness of his points. Mr. Bulmer having obtained a carriage for his conveyance, travelled with him five weeks, and then sold him and the carriage, at Rotherham, to Mr. John Day, on the 14th of May, 1801, for £250.

On the 14th of May, Mr. Day could have sold him for	- -	£525
On the 13th of June for	-	1000
On the 18th of June for	-	2000

Mr. Day travelled with him nearly six years, through the principal parts of England and Scotland, till at Oxford, on the 19th February, 1807, the ox dislocated his hip bone, and continued in that state till the 15th April, when he was obliged to be slaughtered, and, notwithstanding he must have lost considerably in weight during these eight weeks of illness, his carcass weighed,

		Imp. stones,	lbs.
Four quarters,	- -	165	12
Tallow,	- - -	11	2
Hide,	- - -	10	2

This was his weight at eleven years old, under all the disadvantages of travelling in a jolting carriage, and eight weeks of painful illness. Had he been kept quietly at Ketton, and fed till seven years old, there is little doubt but he would have weighed more than he did at ten years old, at which age Mr. Day stated his live weight to have been nearly thirty-four hundred weight, or two hundred and seventy stones, from which if fifty be taken for offal; it leaves the weight of the carcass two hundred and twenty stones.

It is a well ascertained fact, that, during his career as a breeder, Mr. Colling tried several experiments in crossing, and the breeds to which he resorted on these occasions, being very considerably smaller than the short-horns, this circumstance tends to corroborate the writer's opinions that he considered it desirable to reduce their size. The cross with the Kyloe led to no results worthy enumeration, but that with the *Polled Galloway* must not be passed over without comment. Before stating the circumstances attending this experiment, it may be proper to observe that no breed of cattle promised so successful a cross with the short-horns as the Galloway. They were calculated, by their deep massive frames and short legs to bring the short-horns nearer the ground, and to dispose their weight in a more compact manner: their hardy habits would be essentially useful, and the quality of their flesh and hair were such as to render the experiment still more safe. Add to this, that they could be obtained of a red color, and we are prepared to admit, even without the sanction of a successful experiment, that they were admirably adapted to cross with the short-horns, standing frequently too high from the ground, not very well ribbed home, and not seldom of loose, disjointed frame.

To this breed Mr. Colling resolved to resort; and though at the time when he did so, the event was regarded with some degree of ridicule by the pure blood advocates, and comments passed which would have deterred ordinary men from the exercise of their judgement, Mr. Colling persisted.

He was much favored by circumstances in promoting his object which was to take one cross, and then breed back to the short-horn—the only course, by the way, in which crossing can be successfully adopted. To breed from the produce of a cross *directly among themselves* will lead to the results which have induced many persons, without due consideration to believe conclusive against crossing; but to take one cross, and then return and adhere to one breed, will in the course of a few generations, be found to stamp a variety with sufficient certainty.

Mr. Colling's short-horned bull *Bolingbroke* was put to a beautiful red polled Galloway cow, and the produce, being a bull calf, was in due time, put to *Johanna*, a pure short-horn—she also producing a bull calf. This grandson of Bolingbroke was the sire of the cow *Lady* by another pure short-horned dam and from Lady has sprung the highly valuable family of improved short-horns, termed, in reproach, the *alloy*. How far the alloy was derogatory, let *facts* testify.*

It will probably be admitted that the prejudice against this cross was at the highest at the time of Mr. Charles Colling's sale. The blood had been little, if at all, introduced to other stocks, and it was manifestly the interest, whatever might be the inclination, of the many breeders who had it not, to assume high ground for the pure blood, and to depreciate the alloy. Under these untoward circumstances for the alloy, what said public opinion, unequivocally certified by the stroke of the auction-

---

rode home together, they agreed that it should be a joint speculation.

Some months passed by, and either Mr. Waistell's admiration of the calf a little cooled, or his partner did not express himself very warmly about the excellence of the animal, and Messrs. Waistell and R. Colling transferred young Hubback to Mr. Charles Colling; who, with the quick eye of an experienced breeder, saw the value of the little beast. Mr. Waistell expressed to us (October, 1823,) his regret [natural enough] at having been induced to part with the sire of the short-horns, and his extreme disappointment that when Hubback began to cover, Mr. Charles Colling confined him to his own stock, and would not let him serve even one of Mr. Waistell's cows.—*Farmer and Gardener.*

* The dam of Lady was also the dam of the bull Favorite; and as the grandson of Bolingbroke is not known to have been the sire of any other remarkable good animal, it is most probable that the unquestionable merit of Lady and her descendants is to be attributed more to her dam than to her sire.—*Farmer and Gardener.*

eer's hammer? *Lady*, before mentioned, at fourteen years old, sold for two hundred and six guineas. *Countess*, her daughter, nine years old, for four hundred guineas. *Laura*, another daughter, four years old, for two hundred and ten guineas. *Major* and *George*, two of her sons, the former three years old, the latter a calf, for two hundred guineas, and one hundred and thirty; besides a number of others, more remotely descended from Lady, which all sold at high prices; in fact, in a sale of forty-eight lots, realizing £7115 17s. Lady and her descendants sold for a larger sum than any other family obtained.

The whole particulars of the first grand sale of short-horned stock ought to be preserved. We extract it from Mr. Bailey's Survey of Durham.

PARMESAN CHEESE—IRRIGATED LANDS.

The country between Cremona and Lodi comprises the richest part of Milanese. The irrigation too is brought to the highest state of perfection. The grass is cut four times a year as fodder for the cows, from whose milk is made the well known cheese called Parmesan. The cows, which are kept in the stall nearly all the year round, are fed during summer on two of these crops of grass or clover, which are cut green, and in the winter on the other two, which are hayed. The milk of at least fifty cows is required for the manufacture of a parmesan cheese. Hence, as one farm rarely affords pasture for such a number, it is usual for the farmers or metayers of a district to club together. The milk of 50, 60, or even 100 cows, is brought twice to the farm where the dairy is fixed; the person on whom devolves the task of making the cheese, keeps an account of the milk received, and the cheese is afterwads apportioned accordingly. In this fertile plain a farm of sixty acres is considered as a large one. These farms are subdivided into fields of three or four acres, for the convenience of irrigation; a practice which, in the course of a few years, impairs the quality of the grass to such a degree, that it becomes necessary to discontinue it. In this case, the sluices of the Gora are shut, the ground is ploughed in autumn, and in the following spring sown with hemp, which shoots up to a great height; when this is pulled, the ground is sown with leguminous plants. In the next spring it is sown with oats, which grow to the height of six or seven feet. The richness of the soil being thus sufficiently subdued, it is next cropped with wheat. Maize is then sown in the following spring; a second crop of wheat succeeds, and finishes the course of cropping. The ground is then left to itself, and is immediately covered with herbage. During winter it is manured, and the new meadow is then subjected again to the process of irrigation, which is usually continued for fifteen years. Thus the rotation in the Milanese extends to twenty years; five years for the growth of hemp, pulse, and grain, and fifteen for the growth of grass. Rice is also grown in some parts of the Milanese; but as it partakes of the nature of an aquatic plant, for the rice grounds are kept under water during nearly the whole period of its growth, its cultivation has been placed under considerable restriction by the government, owing to the malaria which it engenders.

From the Silk Culturist.

VIRGINIA SILK.

Mr. Forrest Shepherd, of New Haven has presented us with a specimen of the Bombyx Virginiensis, or the native silk worm of Virginia. It is found in great numbers on the Plantation of J. B. Gray, Esq. Stafford Co., and is capable of enduring the most rigorous winter. The cocoons are found suspended upon the red cedar, and yield a beautiful white silk of a strong thread.

The future history of this insect will be particularly interesting to all engaged in the culture and manufacture of silk. Mr. Shepherd, who is soon to visit Virginia, has kindly promised to give us farther information on the subject.

From the Silk Culturist.

THE VALUE OF A FEW MULBERRY TREES.

A few years since, a farmer purchased a farm in the town of Mansfield, on which were standing twelve mulberry trees of full growth. Not being accustomed to the business of making silk, he supposed them to be of no more than the ordinary value of forest trees for fuel. A neighbor, however, soon called upon him, and agreed to pay him twelve dollars annually, for the privilege of picking the leaves. The farmer, to his astonishment, found that the twelve mulberry trees were as good to him as $200, at six per cent. interest.

FORMS FOR AN OVERSEER'S JOURNAL AND MONTHLY REPORTS, SUITED TO A SOUTHERN PLANTATION.

[The gentleman who sends the following forms, has long been engaged in planting on a very large scale, and therefore his experience is worth far more than any opinion we could offer of the usefulness of the plan. It should be observed that in the copy below, the mere plan is presented: the blank spaces, which would be required on a sheet for use, are here necessarily reduced in size, or omitted. In blank forms printed on a large sheet, to receive the actual entries, the "Journal of plantation ——, for the month ——," should occupy two entire pages facing each other—and the other two pages would give room for the several other accounts. If the blank space left at the end for "General Remarks," should not be sufficient, it could be easily enlarged by adding a blank leaf to that particular monthly report, without affecting the regular order and form of the reports.]

To the Editor of the Farmers' Register.

I send you a copy of a plantation journal which I have had made and printed after my own experience, with the request that you will subject it to the examination of practical planters, and if approved, present it the "agricultural society" of your district, with my highest respects.

The intercourse of experience, founded on practical knowledge is the only solder of an agricultural community: and every individual is bound not only by his duties to others, but by his own interests, to extend and nourish this useful interchange of systems. It is from this principle that, humble as the gift may be, I tender to you the first offspring of my own exertions—and I can only hope that like the "widow's mite," the acceptance may be secured by the purity of my motive.

You will observe that the journal is adapted for a period of one month, and is intended to be bound in boards of twelve sheets for a volume—thus forming an authentic record annually, of the operations on the estate, and serving thereafter as a reference for seasons, crops, expenses, &c. I conceive that the simple and concise form of this sheet, will enable any overseer to keep it correctly, as he will have nothing to do save to fill up the heads and columns—and when proprietors travel for the summer, or reside off their plantations, this sheet neatly folded, will as a letter, inform them of all the operations of the farm, and even its daily proceedings.

GENERAL REMARKS, &c.

ON THE SPAYING OF COWS, AND ITS EFFECT UPON THE SECRETION OF MILK.

A private letter from a farmer in Goochland contains the following inquiry and remarks:

To the Editor of the Farmers' Register.

"I wish to make an inquiry of your correspondents, through the Register. It is, whether any one can say with certainty, how long a cow, *spayed* when she is in full perfection, and giving the greatest quantity of milk, will continue to give milk in full quantity, if properly attended to?

"Next to the stock enclosing system, (which the repeal of the present law of enclosures would cause,) the above fact, if it be (as I have been told,) a fact, that cows will continue to give milk plentifully as long as they live, would be of the greatest importance to the poor people. They would not then have to wait, every year, for a half starved cow to have a calf, before their children could get a supply of milk to keep them from suffering for suitable food. They would have a supply for years, and that from an animal easily kept, as spayed animals always are. Small as this thing may seem to be to those who abound in the good things of this life, it is an important matter to be established as regards the poor—and middle classes too."

While joining with our correspondent in the request that others will state whatever facts they may know on this subject, we will offer such information as we are possessed of, and which, though not derived from personal experience, appears to be as well authenticated.

The only publication which we have ever met with on the spaying of milch cows, is contained in a late French periodical—though it is there stated that the advantage of this operation was first discovered by a Mr. Winn of our own country: and no other facts than his had been previously made known, nor are any given by the French writer, except the few repetitions of the experiments in Switzerland, the report of which we will present below. It is singular that so little should be known of the operation in the country in which it originated. It is not stated from what American publication the knowledge of Mr. Winn's practice was learned, and we have to confess our entire ignorance as to the source of information, as well as of the person mentioned.

Before proceeding to give the translation of the French article, we will state a fact within our knowledge, that the spaying of milch cows was practiced on the farm of a deceased friend, John Edmunds of Sussex; and that when we saw the cows and were informed by him of the facts, he was perfectly satisfied with his success, and entertained no doubt of the cows continuing to yield milk without diminution, so long as they were properly kept, and properly milked. The only doubt seems to be whether the secretion of milk will continue through the healthy life of the animal, or only for a time unusually long compared to that of breeding cows—say for several years. We were then struck with the obvious advantages of having a few permanent milkers, which with care and attention would yield regularly as much milk as thrice their number in the ordinary way—and at the same time getting rid of all the trouble of the continual changes of cows, and fluctuations (natural and artificial) of their yield of milk. The want of any person capable of performing the operation with facility and safety prevented our making the experiment. By the way—it appears below that the art of castrating domestic animals is thought in Europe not beneath the attention of government—and that able veterinary surgeons are employed to give courses of instruction to the common operators. So long as such operations are performed here by ignorant negroes, or others but little better informed, there would be greatly increased hazard of death, or of injury to cows in spaying. But there can be no doubt that if proper knowledge and skill are used, that the operation is easily performed, and perfectly safe. It is scarcely necessary to observe that spaying will not serve its intended purpose, if the cows afterwards are as badly treated and milked after the usual manner of lower Virginia—that is, to take from the cow a little less milk every week, if not every day, until she "goes dry." Our milk maids consider this to be the regular order of things; and it would be very difficult to convince them of the possibility of "flying in the face of nature," and of their established usage, by spaying cows.

Without any view of milking qualities, this operation has been used by some of the old "good livers" of lower Virginia, on heifers, for the purpose of making superior beef.

We proceed to give the article entire.

Translated for the Farmers' Register, from the *Recueil de medecine veterinaire pratique.* February 1834.

Mr. Winn, a proprietor in North America, has been the first to report that he has spayed cows, and preserved during many years the quantity of milk which they gave at the time of the operation. The action of the udder neither being injured by the function of gestation, nor by the animal being in heat, it may be conceived that the secretion of milk may continue. Many proprietors, especially those who are situated near great cities, where the high price of milk makes it unprofitable to raise calves, would derive great advantage from keeping cows whose milk would not dry up.

But the observations of Mr. Winn were not numerous, and besides, he has not indicated what method of spaying he used for his animals. We need new observations and more precise details. M. Levrat, a distinguished veterinary surgeon of Lausanne, from whom many communications have been inserted in the *Récueil de médecine vétérinaire*, reports his manner of performing this operation on the cow, and the physiological results which he has remarked after two cases. The number of facts still needs to be increased: they ought also to be observed longer, before a decided opinion is formed of the dangers and consequences of the operation. However, the notice which M. Levrat has inserted in the *Journal des Connoissances utiles* will doubtless be interesting to our readers. We give in the author's words:

"In May 1832 I was entrusted by the government of the Canton de Vaud, with the direction of a course of instructions for the country operators in the art of castration. The opportunity to repeat the experiments made in America on spaying cows, was too favorable to be missed. I performed the operation of extracting the ovaries of a cow, which was intended to be sacrificed to illustrate the course of instruction. This cow not giving milk, my object could not be completely attained. Nevertheless, it was no small gain to have studied the manual part of this operation, and to have assured myself of its pathological effect, in order to be able, on the one hand, to practice this operation with assurance, and on the other, to inspire with more confidence the owners of cows who might be willing to make the trial. My attempt was quite successful. The cow operated on did not seem to be made sick by it: during the two days which followed the operation she appeared rather drooping [*un peu triste;*] but by the third day she was as lively as before, and returned to her usual habits.

"The object then was to perform the operation on cows that were in the condition indicated by Mr. Winn, that is to say, a month after their second or third calving.

"M. Francillon Michaud, to whom I gave information of this discovery, was desirous of submitting one of his cows to the experiment. This cow, six years old, then had her third calf. The preceding years, she had given, soon after her calving, eight quarts [*pots*]* of milk, and six quarts at a later period. This cow was operated on, June 23d, 1833, thirty-eight days after calving. The consequent sickness was but slight: only it was observed that during the two days which followed the operation she had less appetite: her milk was lessened four quarts—but the third day she recovered her appetite, her liveliness, and returned to her previous quantity of milk. During the whole summer she continued to give about nine quarts; and since the supply of green food has ceased, and she has been kept on dry forage, she has kept at seven quarts—while the preceding years, as before stated, she gave [under like circumstances] but six quarts.

"Encouraged by this first success, M. Francillon requested me to make a second trial. For this, he chose an old cow, that yielded milk abundantly, in order to form a judgement of this operation upon aged cows. This one was twelve years old, and had produced twin calves on the 17th of October, and had sustained injury in giving them birth. She had yielded, in preceding years, on an average, eight quarts of milk. She was spayed on Nov. 18th, thirty-three days after calving. She gave at that time twelve quarts of milk. After the operation she lost three quarts: but it is proper to state that this cow has a discharge of matter from the womb, and that she neither eats nor digests as usual, and that it will be otherwise when she is in good health.†

"The authors of the article upon the spaying of the cow have not directed the manual part of the operation; yet it is so much the more important to know, as the ovaries vary in their position, according to the species. I do not know that any author has given the necessary directions. Daubenton has spoken of the manner of spaying ewes, and after him, Fromage of Feugre: but the practice on the ewe is not applicable to the cow: it is therefore that I am going to describe the mode of operation which I have tried, and found successful.

"The operation should be performed at from 30 to 38 days after the calving, upon a cow that has had her second or third calf, because that is the period at which a cow yields the most milk, and after which it may be enjoyed for a long time. There is no precaution necessary, save that of not permitting the cow to have a full meal the preceding evening, and to operate in the morning before she eats again. The things required for the most convenient mode of practice, are, some cords, a plank or bar of wood, two surgical knives [bistouris,] the one convex on the edge; the other straight, and with a guard on the point [boutonné]—two needles bent for stitching, with stout twisted thread, well waxed, two pegs of dry wood, eight inches long and of the diameter of about a quarter or third of an inch.

"*Manner of fixing the cow.*—To be enabled to operate in perfect security, it is necessary to fix the animal suitably. To this end she is placed against a wall, the left side turned towards the operator. This wall ought to have three buckles fixed to strong rings. One of these rings is for the cord that confines the head; the other two should be placed lower, one at the level of the lower part of the right shoulder; the other at the point of the knee bone—or an assistant may hold the cord to produce the intended confinement. The head is fixed by the cord being tied; or otherwise held by a strong assistant. Then the plank or bar is placed obliquely under the udder, forward of the posterior members—and is held by an assistant to protect the operator from the feet of the cow. The tail is also held, or it may be tied to the rope which passes round the animal, to prevent the blows from it which might be received (if unconfined) when the operator introduces his arm into the abdomen.

"For want of a wall, provided with rings and buckles, use may be made of a strong paling, a solid gate or fence, or even of trees standing at suitable distance, to which is fixed a large wooden bar.

"The animal being securely fixed, the operator armed with the knife with the convex edge, which he holds in his right hand, places himself near the left shoulder of the cow, the left hand applied to her back: this hand gives a point of support to lean on, if made necessary by the unruly movements of the animal: and this support gives more steadiness to the right hand. He carries the edge of the knife to the middle (and a little nearer the upper part) of the left flank, and with a single stroke, he cuts vertically through the skin and the muscles of this part.

"The flank having thus been opened to the *peritonæum*, [the membrane which envelopes the bowels,] the operator enlarges the incision with the guarded knife, so as to be able to pass his arm. He introduces his hand into the abdomen, directing it against the cavity, behind the bottom [*cul-de-sac*] of the paunch, where are found the horns of the uterus. As soon as he meets with this

*This measure *(pot)* is equal to two French pints—but still may be different from two American pints, as rendered above. No mistake in this respect, however, will affect the comparison of quantities yielded before and after the operations.—ED. F. R.

†It may be supposed that the time of year, and consequent diminution of green and juicy food, also had some effect in keeping down the quantity of milk in this case.—ED. F. R.

organ, where the ovaries are situated, between the thin bands [or membranes] of the ligaments suspending the uterus, he seizes one of the ovaries, which he detaches from its posterior part with the thumb and fore-finger; he passes this over the convexity of the ovary, to separate it completely from the peritonæal ligament, which sustains it: then he seizes the ovary in his hand, draws it gently, and by means of the thumb nail, he scrapes the vessels and the fallopian tube upon the fore finger, which presents a point of support under these vessels. Finally, he breaks the cord, which is the object in view, by gently drawing it, as he makes it undergo the scraping with the nail, and the ovary is brought out. He then again introduces the hand into the abdomen, and proceeds in like manner to extract the other ovary. Then the wound is closed by stitches secured with the wooden pegs, taking care not to close entirely the lower part, in order not to hinder the discharge of the matter, which, without this precaution, would spread between the skin and the muscles, and within the abdomen, and might cause ill effects which are avoided by favoring its passage out.

"The ovaries may also be drawn out of the opening made in the flank, and then detached with the ends of the fingers: but this mode may be attended with inconveniencies. Besides, it is not more expeditious than the course I have directed, because it often happens that the ovary escapes from the hand, and that the operator has again to introduce his arm to search for it.

"Two or three days after the operation, the wound must be dressed. For the dressing it is only necessary to foment twice a day all around the wound with lukewarm mallows—to keep it clean, and in warm weather to inject in the wound the water of Labarraque. Every time of dressing the wound; the aperture should be covered with a little tow placed between the two pegs, to prevent any dirt getting in, and which is secured with thread in its place. The wound being properly dressed twice a day, will cure of itself in fifteen days, or at most three weeks.

"It is seen from what has been stated above, that the effect of spaying is not merely as has been said, to keep the milk producing faculties at the height at which they were before the operation, but rather at a height *above the previous degree of those faculties;* which, without contradiction, is an important advantage, and especially if it is true that this faculty is preserved during many years.

The wounds of the cows of M. Francillon on which I operated, were dressed by his servant—and thus it ought to be managed, to avoid the expense of having the dressings attended to by a veterinary surgeon. For if this practice should spread, it is necessary to make it cheap, that it may occasion as little expense, and render as great advantages to proprietors as possible, and such as I hope they will derive."

From the Fruit Cultivator.

SOILS SUITABLE FOR APPLE TREES. MR. KNIGHT'S OPINION OF GRAFTED TREES ERRONEOUS.

Deep rich soils, in sheltered situations, are not the most proper for the apple, though such have been most erroneously recommended by writers who ought to have known better. For it is often seen that apple trees succeed well in any kind of loam, though it be not more than one foot in depth, so as the bottom is sound and dry: the roots take an extensive horizontal range, the young wood is always of more moderate growth, and better ripened than where roots strike deep into the ground.

The golden pippin being one of our most useful and esteemed hardy fruits, the author trusts he will be forgiven for entering more at large into its history and management than he has thought necessary in the preceding notices of other inferior kinds of apples, especially as there has been, for several years past, an idea prevalent, that this country was about to lose this fine fruit forever. In Mr. Knight's *Treatise on Orchard Fruit*, the doctrine was first broached, that all our varieties and sub-varieties of fruits have but a temporary existence. They are raised from seed, to flourish for an uncertain number of years, and, after arriving at their maximum of health and fertility, gradually sink to decay, and at length disappear. Taking this idea as a rule, the golden pippin was judged to be in this last stage of existence; and it was predicted, that not only were the old full grown trees to disappear, but all the young ones, lately worked from them, would perish also. It must be admitted, that a great majority of the old golden pippin trees in Herefordshire, and in other parts of the kingdom, were, about the time Mr. Knight wrote his treatise, in an apparent state of decay; and, moreover, that young trees of the same sort could but with difficulty be made to grow and bear so freely as they had previously done. These failures, however, were accounted for in another way than that propounded by Mr. Knight. It was observed, that the old trees, having probably all been planted about the same time, and having arrived at their natural period of healthy existence, were like all other trees, falling to decay from sheer old age; and that the contemporaneous weakness and debility of the young lately planted trees were caused by a careless choice of grafts, by working them on improper stocks, and planting them in old worn out soil, instead of in fresh, well trenched, light, loamy situations. This latter opinion was the more feasible, because there were many middle aged trees in different parts of the kingdom, which were in full vigor and bearing; and though young plants planted in old gardens and orchards were unthrifty such as were properly planted in newly broken up ground, provided they were worked on the best crab stocks, succeeded as well as ever.

This being the opinion of the author respecting the failure of the old golden pippin, and all other sorts of apples, he gave the subject his best consideration, and set about proving how far his own conjectures were well or ill founded; and, after the experience of forty years, he has come to the following conclusion; viz., that if crab stocks be raised from the most healthy wild trees, properly treated, and planted out in the nursery, and worked with the most healthy moderate sized scions, cut from the top of sound healthy trees, and, when fit for final transplantation, be placed on well trenched light fresh loam, having a dry bottom of rock or chalk, the trees will assuredly prosper without fear of disappointment. On the other hand, if the graft be taken indiscriminately from any tree, or from any part of a tree, and placed either on free or paradise stocks, the young trees so raised will, nine times out of twelve, be in some respect or other defective: and particularly if they be not afterwards planted in their favorite soil, where their wood would not be sufficiently ripened.

The golden pippin requires a dry and moderately warm climate. The best fruit are produced in Normandy on the continent, in Sussex in England, and on walls in Scotland. The south of France is too warm, and the richer counties of England and Ireland are too moist. This apple is supposed to have been first raised at Parham Park, on the Southdowns of Sussex.

It has been noticed of late years, that neither the golden pippin nor Nonpareil keep so well as formerly. The author well remembers, that, sixty years ago, both these kinds of apples were plentiful in May; but it is not so at present. This is attributed to two causes; our summers lately being more moist, and perhaps too many free and paradise stocks used in their nurseries. It has been deemed a good practice to raise the golden pippin from cuttings or layers. This plan is quite practicable; and some practitioners have been very successful in raising plants from cuttings, intended for potting. Trees may also be raised by layers from stools kept on purpose in the nursery.

THE MEANS OF RECOVERING AND PRESERVING YARDS FROM FOUL WEEDS.

To the Editor of the Farmers' Register.

Ben Lomond, June 6th, 1835.

Though the subject of the following communication may be considered by yourself as unworthy of a place in your periodical, yet I feel that it contains information interesting to at least a small portion of your readers. In this communication, I shall make no pretensions to *originality* or *discovery*, as my information was derived from an intelligent lady near me. She informed me that her yard was at one time infested with (I use her own words) all kinds of foul weeds, the common old field broom straw, &c. &c. While on a visit to her this spring, I was struck with the peculiar beauty of her yard, and its purity from all "foul weeds." I inquired the cause, as it was a subject of interest to me, having seen many beautiful sites for yards, destroyed by allowing the foul weeds to take possession of them.

Her *modus operandi* is simple, but which I fear will be no recommendation. At any time in the spring, (before a rain is preferable) if ashes are scattered over the yard, in a short time all the foul weeds will be rooted out, and in their place will come a beautiful bed of the greensward grass. The ashes should be scattered frequently, always before a rain, (I suppose during the year.)

Query.—Would not the sulphate of lime (plaster of Paris) accomplish the same object? Whether the ashes act as a manure, thereby facilitating the growth of the grass, or whether they destroy the weeds, I am unable to say, though I think the former supposition the most probable. This communication is induced from the reflection, that there can be no ornament more superlatively beautiful, than a handsome yard about a handsome building—and trusting that these ideas will serve a useful purpose, I am willing to submit them to your discretion, though not clothed in such a garb as I could wish for your truly useful paper.

As I highly approve of a piece which I met with in your paper, suggesting the idea that all communicators should affix their true name, I subscribe myself,

T. B. WATKINS,
Of Goochland.

[The facts stated above are not only interesting as furnishing matter for useful and often needed practice, but because they also serve to illustrate the views already expressed in other articles in the early part of this No. (pp. 129 and 130.) The principal, if not the sole agent of the change produced by the application of ashes, was the calcareous earth which they contained—of which earth, the benefit to greensward is as remarkable as to clover. Broom grass is not, usually, at once destroyed by the use of this manure, (as sheep sorrel is,) but the growth is evidently injured by calcareous manures, so as to induce the belief, that the destruction will be complete in time. We have only in one case observed the almost complete destruction of the growth of broom grass, which was previously the unmixed cover of a worn-out old field. This was also produced by top dressing—but with marl, instead of ashes. The piece of ground (about an acre) was neither ploughed nor grazed for several years after; and by the third summer, the broom grass had generally disappeared, and was substituted by other weeds, except in some small spots which it was supposed the manure did not reach. After ploughing in marl, and even after several years of tillage, broom grass will return, and even grow luxuriantly—but it is in separate and scattered bunches, instead of forming a regular and unmixed cover to the land, as before marling.

We are the more pleased to be indebted to a *lady* for this experiment—and hope that it may be noticed and repeated by other ladies who can, and will, in other matters, return equal value to the Farmers' Register—which might be well done by many.]

RICH CALCAREOUS EARTH FOR MANURE IN THE NORTH-WEST PART OF PENNSYLVANIA.

[The following article is taken from a late Meadville Messenger, sent us by the editor. We should infer, from the description, that the earth was like the "rotten limestone" which lies under all the prairie soils of Alabama—and, as appears from Mr. Featherstonhaugh's Report, (see extract at page 147 of this No.) also of the great prairies west of the Mississippi. The fact stated below, presents additional proof, and derived from a different and remote region, of the truth of the opinion which we have before submitted, that the cause of the peculiar features of prairie soils, particularly of the absence of trees, was merely *the presence, in such soils, of a large proportion of lime.* The fact of the earth here called *marl* being made into the "best lime" by burning, is sufficient evidence of the great richness of the material, and its suitableness for manure. Crawford County is in the north-west part of Pennsylvania, and on the border of Lake Erie.]

About eleven miles north west of this place, (three or four miles north of Brightstown in this county, Crawford, Pa.,) an inexhaustible bed of the *carbonate of lime* in a clayey state (*calcareous marl,*) has been discovered. The clay when burned after the usual manner, produces very good white lime, from the specimen we have seen we would say the *very best lime.* It has been found that at this one place, it covers an extent of one hundred acres, which is prairie land covered with turf to the depth of one foot, under which the marl is found, and although it has been dug to the depth of nine feet, yet no sign of other kind of earth was discovered. Apart from the general uses to which lime is applied, we are sensible that this discovery will effect a new era in the *agriculture* of this section of country, and will, when its uses as a fertilizing manure become extensively known and applied, enhance the value of our lands, two-fold. We hope this discovery will excite such a spirit of inquiry and research as will result in the disclosure of beds of lime in every part of the county; and that persons may be disposed to seek for it from an acquaintance with its nature and uses, and be able to distinguish it from other earths, we shall in some future number devote a column in explanation of its chemical properties, probable localities, and value as a manure. We have no idea that it is confined to any particular spot, but from many circumstances, are firmly of opinion that it will be found near the surface in almost every section of the county.

From the Library of Useful Knowledge—Farmer's Series.

THE VICES, AND DISAGREEABLE OR DANGEROUS HABITS OF THE HORSE.

[Continued from page 104, Vol. III.]

Horses have many unpleasant *habits* in the stable and the road, which cannot be said to amount to *vice*, but which materially lessen their value.

Swallowing without grinding.

Some greedy horses swallow their corn without properly grinding it, and the power of digestion not being adequate to the dissolving of the husk, no nutriment is extracted, and the oats are voided whole. This is particularly the case when horses of unequal appetite feed from the same manger. The greedy one, in his eagerness to get more than his share, bolts a portion of his corn whole. If the farmer can, without considerable inconvenience, so manage it that every horse shall have his separate division of the manger, the horse of smaller appetite and slower feed would have the opportunity of grinding at his leisure, without the fear of his share being stolen from him by his neighbor.

Some horses, however, are naturally greedy feeders, and will not, even when alone, allow themselves time to chew or grind their corn. In consequence of this, they carry but little flesh; they are not equal to severe work; and, if their rack has been supplied with hay when the corn was put into the manger, their stomachs will become distended with half-chewed and indigestible food; they will be incapable of exertion for a long time after feeding, and, occasionally, dangerous symptoms of staggers will occur. The remedy is, not to let such horses fast too long. The nose-bag should be the companion of every considerable journey. The food should likewise be of such a nature that it cannot be easily bolted. Chaff should be plentifully mixed with the corn, and in some cases, and especially in horses of slow work, should, with the corn, constitute the whole of the food. Of this we shall treat more largely under the article 'feeding.'

In every case of this kind the teeth should be very carefully examined. Some of them may be unduly lengthened, particularly the first of the grinders; or they may be ragged at the edges, and may scratch and wound the cheek. In the first case the horse *cannot* properly masticate his food; in the latter he *will not:* for these animals, as too often happens in sore throat, would rather starve than put themselves to much pain.

Crib biting.

This is a very unpleasant habit, and a considerable defect, although not so serious a one as some have represented. The horse lays hold of the manger with his teeth, violently extends his neck, and then, after some convulsive action of the throat, a slight grunting is heard, accompanied by an apparent sucking or drawing in of air. Whether, however, air is actually drawn in, and thus the horse becomes more subject to colic than one without this trick, or whether a portion of air is expelled, showing the previous existence of flatulence and a disposition to colic, are points that have not been settled among veterinarians.

The horse is evidently making the edge of the manger a fixed point, by means of which he may overcome that obstacle which the formation of the soft palate and the back part of the mouth would present to either the expulsion or drawing in of the air, if accomplished through the medium of the mouth. When we consider, however, that any air expelled from the stomach might easily find a passage through the nostril, without the action of crib biting; while it would be difficult or impossible, without some alteration in the natural form and action of the parts at the back of the mouth, and particularly the depression of the epiglottis or covering of the windpipe, to convey air to the stomach, we are inclined to conclude, that this fixed point is used to enable the animal to accomplish this alteration, and suck up and convey a portion of air into the stomach.

The effect of crib biting is plain enough. The teeth are injured and worn away, and that, in an old horse, to a very serious degree; a considerable quantity of corn is often lost, for the horse will frequently crib with his mouth full of corn, the greater part of which will fall over the edge of the manger; and much saliva flows out while the manger is thus forcibly held, the loss of which must be of serious detriment, as impairing the digestion. The crib biting horse is notoriously more subject to colic than other horses usually are, and to a species difficult of treatment, and even dangerous. Although many a crib biter is stout and strong, and capable of all ordinary work, these horses do not generally carry much flesh, and have not the endurance of others. On these accounts, crib biting has very properly been decided to be unsoundness.

It is one of those tricks which are very contagious. Every companion of a crib biter in the same stables is likely to acquire the habit, and it is the most inveterate of all habits. The edge of the manger will in vain be lined with iron, or with sheep-skin, or with sheep-skin covered with tar or aloes, or any other unpleasant substance. In defiance of the annoyance which these may occasion, the horse will in a very short time again attack his manger. A strap buckled tightly round the neck, by compressing the windpipe, will prevent the possibility of this action; but the strap must be constantly worn, and its pressure is too apt to produce a worse affection, viz. an irritation in the windpipe, which terminates in roaring.

Some have recommended turning out for five or six months; but this has never succeeded except with a young horse, and then rarely. The old crib biter will employ the gate for the same purpose as the edge of his manger, and we have seen him gallop across a field for the mere object of having a grip at a rail. Medicine will be altogether thrown away in this case.

The only remedy is a muzzle, with bars across the bottom; sufficiently wide to enable the animal to pick up his corn and to pull his hay, but not to grasp the edge of the manger. If this be worn a very long time, the horse may be tired of attempting that which he cannot accomplish, and may possibly for a while forget the habit; but in the majority of cases the desire of crib biting will return with the power of gratifying it.

The causes of crib biting are various, and some of them beyond the control of the proprietor of the horse. We have said that it is often the result of imitation; but it is more frequently the consequence of idleness. The high-fed and spirited horse must be in mischief, if he is not usefully employed. Sometimes, but we believe not often, it is produced by partial starvation, whether in a bad straw-yard, or from unpalatable food. An occasional cause of crib biting is the frequent custom of grooms, even when the weather is not severe, of dressing them in the stable. The horse either catches at the edge of the manger, or at the edge of the partition on each side, if he has been turned, and thus he forms the habit of laying hold of these substances on every occasion.

Wind-sucking.

This bears a close analogy to crib biting. It arises from the same causes; the same purpose is accomplished; and the same results follow. The horse stands with his neck bent; his head drawn inward; his lips alternately a little opened and then closed, and a noise is heard as if he were sucking. If we may judge from the same comparative want of condition, and the flatulence which we have described under the last head, either some portion of wind enters the stomach, or there is an injurious loss of saliva. This diminishes the value of the horse almost as much as crib biting; it is as contagious, and it is as inveterate. The only remedies, and they will seldom avail, are tying the head up, except when the horse is feeding, or putting on a muzzle, with sharp spikes towards the neck, and which shall prick him whenever he attempts to rein his head in for the purpose of wind-sucking.

Cutting.

Of this habit we have already spoken at page 252, and we would advise the owner of a cutting horse, without trying any previous experiments of raising or lowering the heels, to put on the cutting foot a shoe of even thickness from heel to toe, not projecting in the slightest degree beyond the crust, and the crust itself being rasped a little at the quarters; and to let that shoe be fastened as usual on the outside, but with only one nail on the inside, and that almost close to the toe. The principle on which this shoe acts has been explained at page 243.

Not lying down.

It not uncommonly happens that a horse will seldom or never lie down in the stable. He sometimes continues in apparent good health, and feeds and works well; but generally his legs swell, or he becomes fatigued sooner than another horse. If it is impossible to let him loose in the stable, or to put him into a spare box, we know not what is to be done. No means, gentle or cruel, will force him to lie down. The secret is that he is tied up, and either has never dared to lie down through fear of the confinement of the halter, or he has been cast in the night, and severely injured. If he can be suffered to range the stable, or have a comfortable box, in which he may be loose, he will usually lie down the first night. Some few horses, however, will lie down in the stable, and not in a loose box. A fresh, well made bed will generally tempt the tired horse to lie down.

Overreach.

This unpleasant noise, known also by the terms 'clicking,' 'overreach,' &c. arises from the toe of the hind foot knocking against the shoe of the fore foot. In the trot, one fore leg and the opposite hind leg are first lifted from the ground and moved forward, the other fore leg and the opposite hind leg remaining fixed; but, to keep the centre of gravity within the base, and as the stride, or space passed over by these legs, is often greater than the distance between the fore and hind feet, it is necessary that the fore feet should be alternately moved out of the way for the hind feet to descend. Then, as occasionally happens with horses not perfectly broken, and that have not been taught their paces, and especially if they have high hinder quarters and low fore ones, if the fore feet are not raised in time, the hind feet will strike them. The fore foot will generally be caught when it has just begun to be raised, and the toe of the hind foot will meet the middle of the bottom of the fore foot. It is a very disagreeable noise, and not altogether free from danger; for it may so happen that a horse, the action of whose feet generally so much interferes with each other, may advance the hind foot a little more rapidly, or raise the fore one a little more slowly, so that the blow may fall on the heel of the shoe, and loosen or displace it; or the two shoes may be locked together, and the animal may be thrown; or the contusion may be received even higher, and on the tendons of the leg, when considerable swelling and lameness may follow.

If the animal is young, the action of the horse may be materially improved; otherwise nothing can be done, except to keep the toe of the hind foot as short and as round as it can safely be, and to bevil off and round the toe of the shoe, like that which has been worn by a stumbler for a fortnight, and, perhaps, a little to lower the heel of the fore foot.

A blow received on the heel of the fore foot in this manner has not unfrequently, and especially if neglected, been followed by quittor.

Pawing.

Some hot and irritable horses are restless even in the stable, and paw frequently and violently. Their litter is destroyed, the floor of the stable broken up, the shoes worn out, the feet bruised, and the legs sometimes sprained. If this habit does not exist to any great extent, yet the stable never looks well. Shackles are the only remedy, with a chain sufficiently long to enable the horse to shift his posture, or move in his stall; but even these must be taken off at night, otherwise the animal will seldom lie down.

Quidding.

A horse will sometimes partly chew his hay, and suffer it to drop from his mouth. If this does not proceed from irregular teeth, which it will be the business of the veterinary surgeon to rasp down, it will be found to be connected with sore-throat, and then the horse will exhibit some other symptom of indisposition, and the swallowing of water will be accompanied by a peculiar gulping effort. In this case the disease (catarrh, with sore throat) must be attacked, and the quidding will cease.

Rolling.

This is a very pleasant and perfectly safe amusement for a horse at grass, but cannot be indulged in the stable without the chance of his being dangerously entangled with the collar rein, and being cast. Yet, although the horse is cast, and bruised, and half-strangled, he will roll again on the following night, and continue to do so as long as he lives. The only remedy is not a very pleasant one to the horse, nor always quite safe; yet it must be had recourse to if the habit of rolling is inveterate. 'The horse,' says Mr. Castley, in the *Veterinarian*, 'should be tied with length enough of collar to lie down, but not to allow of his head resting on the ground; because, in order to roll over, a horse is obliged to place his head quite down upon the ground.'

Shying.

We have briefly treated of the cause of this vice at page 98, and observed that while it is often the result of cowardice, or playfulness, or want of work, it is at other times the consequence of a defect of sight. It has been remarked, and we believe very truly, that shying is oftener a vice of half or quarter-bred horses, than of those who have in them more of the genuine racing blood.

In the treatment of shying, it is of great importance to distinguish between that which is the consequence of defective sight, and that which results from fear, or newness of objects, or from mere affectation or skittishness. For the first, the nature of which we have explained at page 98, every allowance must be made, and care must be taken that the fear of correction be not associated with the imagined existence of some terrifying object. The severe use of the whip and the spur cannot do good here, and are likely to aggravate the vice ten-fold. A word half encouraging and half scolding, with a gentle pressure of the heel, or a slight touch of the spur, will tell the horse that there was nothing to fear, and will give him confidence in his rider on a future occasion. It should be remembered, however, that although a horse that shies from defective sight may be taught considerable reliance on his rider, he can never have the cause of the habit removed. We may artificially strengthen the human sight, but the horse's must be left to itself.

The shying from skittishness or affectation is quite a different affair, and must be conquered: but how? Severity is out of place even here. If he is forced up to the object by dint of correction, the dread of punishment will afterwards be associated with that object, and on the next occasion, his startings will be more frequent and more dangerous. The way to cure him is to go on, turning as little as possible out of the road, giving the animal a harsh word or two, and a gentle touch with the spur, and then taking no more notice of the matter. After a few times, whatever may have been the object which he chose to select as the pretended cause of affright, he will pass it almost without notice.

In page 225, under the head 'breaking in,' we have described how the colt may be cured of the habit of shying from fear or newness of objects; and if he then be accustomed as much as possible to the objects among which his services will be required, he will not possess this annoying vice when he grows to maturer age.

Mr. John Lawrence, in his last pleasing work on the horse, says, 'These animals generally fix on some particular shying butt: for example, I recollect having, at different periods, three hacks, all very powerful; the one made choice of a windmill for the object or butt, the other a tilted wagon, and the last a pig led in a string. It so happened, however, that I rode the two former when amiss from a violent cold, and they then paid no more attention to either windmills or tilted wagons than to any other objects, convincing me that their shying when in health and spirits was pure affectation, an affectation however, which may be speedily united with obstinacy and vice. Let it be treated with marked displeasure, mingled with gentle, but decided firmness, and the habit will be of short endurance.*'

* 'We will suppose a case, a very common one, an every day one. A man is riding a young horse upon the high-road in the country, and meets a stage coach. What with the noise, the bustle, the imposing appearance altogether, and the slashing of the coachman's whip, the animal at its approach erects his head and crest, pricks his ears, looks affrighted, and no sooner comes alongside of the machine than he suddenly starts out of the road. His rider, annoyed by this, instantly commences a round of castigation with whip, spur, and curb, in which he persists until the horse, as well as himself, has lost his temper; and then one whips, spurs,

Shying on coming out of the stable is a habit that can rarely or never be cured. It proceeds from the remembrance of some ill-usage or hurt which the animal has received in the act of proceeding from the stable, such as striking his head against a low door-way, or entangling the harness. Coercion will but associate greater fear and more determined resistance with the old recollection. Mr Castley, to whom we are indebted for much that is valuable on the subject of the vices of the horse, gives an interesting anecdote, which tends to prove that while severity will be worse than useless, even kind treatment will not break a confirmed habit. 'I remember a very fine gray mare that had got into this habit, and never could be persuaded to go through a door-way without taking an immense jump. To avoid this, the servants used to back her in and out of the stable; but the mare happening to meet with a severe injury of the spine, was no longer able to back; and then I have seen the poor creature, when brought to the door, endeavoring to balance herself with a staggering motion upon her half-paralyzed hind extremities, as if making preparation and summoning up resolution for some great effort: and then, when urged, she would plunge headlong forward with such violence of exertion, as often to lose her feet, and tumble down "altogether most pitiable to be seen." 'This I merely mention,' he continues, 'as one proof how inveterate the habits of horses are. They are evils, let it always be remembered, more easy to prevent than cure.'

Slipping the Collar.

This is a trick at which many horses are so clever that scarcely a night passes without their getting loose. It is a very serious habit, for it enables the horse sometimes to gorge himself with food, to the imminent danger of staggers: or it exposes him, as he wanders about, to be kicked and injured by the other horses, while his restlessness will often keep the whole team awake. If the web of the halter, being first accurately fitted to his neck, is suffered to slip only one way, or a strap is attached to the halter and buckled round the neck, but not sufficiently tight to be of serious inconvenience, the power of slipping the collar will be taken away.

Tripping.

He must be a skilful practitioner or a mere pretender who promises to remedy this habit. If it arises from a heavy forehand, and the fore legs being too much under the horse, no one can alter the natural frame of the beast: if it proceeds from tenderness of the foot, grogginess, or old lameness, these ailments are seldom cured; and if it is to be traced to habitual carelessness and idleness, no whipping will rouse the drone. A known stumbler should never be ridden, or driven alone, by any one who values his safety or his life. A tight hand or a strong bearing-rein are precautions that should not be neglected, but they are generally of little avail; for the inveterate stumbler will rarely try to save himself, and this tight rein may sooner and farther precipitate the rider. If, after a trip, the horse suddenly starts forward, and endeavors to break into a canter, the rider or driver may be assured that others before him have fruitlessly endeavored to remedy the nuisance.

If the stumbler has the foot kept as short and the toe pared as close as safety will permit, and the shoe be rounded at the toe, or have that shape given to it which it naturally acquires in a fortnight from the action of such a horse, the animal may not stumble quite so much; or if the disease which produced the habit can be alleviated, some trifling good may be done, but in almost every case a stumbler should be got rid of, or put to slow and heavy work. If the latter alternative be adopted, he may trip as much as he pleases, for the weight of the load and the motion of the other horses will keep him upon his legs.

Weaving.

This consists in a motion of the head, neck, and body, from side to side, like the shuttle of a weaver passing through the web, and hence the name which is given to this peculiar and incessant action. It indicates an impatient, irritable temper, and a dislike to the confinement of the stable; and a horse that is thus incessantly on the fret will seldom carry flesh, or be safe to ride or drive. There is no cure for it, but the close tying up of the animal, except at feeding time.

---

and pulls, and the other jumps, plunges, frets, and throws up his head, until both, pretty well exhausted by the conflict, grow tranquil again and proceed on their journey, though not for some time afterwards in their former mutual confidence and satisfaction. Should they in their road, or even on a distant day, meet with another coach, what is the consequence? That the horse is not only more alarmed than before; but now, the moment he has started, being conscious of his fault, and expecting chastisement, he jumps about in fearful agitation, making plunges to strike into a gallop, and attempting to run away. So that by this correction, instead of rendering his horse tranquil during the passage of a coach, the rider adds to the evil of shying that of subsequently plunging, and perhaps running away.'—The *Veterinarian*, by Messrs. Percival and Youatt, vol. i., p. 96.

From the Horticultural Register.

ON PARTY SPIRIT IN HORTICULTURE.

Start not, reader; the caption of this article forebodes no bloodshed in America, and however violent the spirit, the subject is merely a *Rose.*

It is in the great commercial, free Hanseatic city of Hamburg, in Germany, that this flame of discord has been kindled, which threatens even to falsify the line of the great delineator of the human character, that,

"A rose by any other name would smell as sweet."

It appears that Messrs. Booth, proprietors of the Flottbeck Nursery, near Hamburg, had raised a new rose from the seed of the old and well known Maiden's Blush, which is described as wonderfully beautiful (wunderschön) and of which they had consequently sold a large quantity. This they called in their catalogue the Queen of Denmark rose.

Professor Lehmann, Director of the Hamburg Botanic Garden, in his descriptive catalogue remarks on a variety of the rose, there called La Belle Courtisanne, that this rose was described in France in 1806 as a hybrid between the old Dutch Hundred Leaf and the Maiden's Blush.

The roses being identical, Messrs. Booth felt the honor of their well regulated nursery at stake, and after some slight warfare in their respective annual catalogues, these gentlemen published a pamphlet on the subject, which was replied to by the Professor in the newspaper. This produced a very bitter and personal rejoinder from Messrs. Booth, in a second pamphlet, which was distributed gratuitously.

The Professor having stated that the rose in question was figured in the magnificent and expensive publication, with colored plates, by the celebrated Redouté, fellow pupil with Audubon, of David the painter, he procured the work and left it out for public exhibition. Redoute's figure was generally considered identical with Booths' Queen of Denmark, although these gentlemen would scarcely allow it.

A hot war of affidavits, letters of proof, and documents now commenced, the most interesting of which is a letter from the distinguished veteran botanist, Thouin, who died in 1826, dated in 1824, which gives some good explanations of the Professor's strong declaration, and shows that the Belle Courtisanne rose, under this name, was sent by Thouin to the Hamburg Botanic Garden, from whence it was also distributed to many other gardens.

Messrs. Booth hereupon published gratis a most offensive pamphlet, entitled "Victory of the Queen of Denmark Rose, unveiling the motives of the attack of Professor Lehmann." To this the Professor published a cool and well written reply; the friends on each side began to publish also—accusation and retorts were liberally scattered and the plague of party spirit spread far and wide. We do not think, however, it will terminate in a continental war.

That elegant German writer, Wieland, in his fiction of the history of the people of Abdera, a town in ancient Greece, relates that a citizen of the town hired an ass; the day being sultry, he took it into his head during his ride, to dismount from the patient animal, and sit down for a time in the shade of the creature's body. The owner demurred to this proceeding, and demanded additional hire, having, as he stated, only let the ass, and not his shadow. After a warm altercation, both returned to the city and went before the magistrate. The question now became altogether one of party, in which no neutrality was permitted, and the whole city was soon divided into two violent sides, one of which obtained the appropriate distinctive appellation of *Asses*, and the other of *Asses' shadows*. During a popular commotion on this quarrel, the innocent cause of it was torn limb from limb—thus even the shadow of an ass was annihilated, and had not some other question of equal importance been started, which threw this into oblivion, the result would no doubt have been disastrous. We disclaim the slightest idea of an offensive application of the above story; it is enough to show how well those understand the human heart who describe a trifle as sufficient to inflame the bad passions of mankind.

The highly talented German botanist, Nees Von Esenbeck, writes two letters on this quarrel, which have been published in the *Allemeine Botanische Zeitung*, (General Botanical Newspaper) commencing in something like the following lively vein:

"How much that is beautiful, joyous, and endearing has been written and said on the rose; how much that is delightful on its character? how many exquisite ideas has it inspired to be breathed by love? The beauty of this flower must sink deepest into our imagination, when its appearance forces us to associate with it every feeling that is tender, delicate, and luxurious. How anomalous, how absurd, then, the idea that the rose can engender feelings of division and strife. I am convinced that in the beautiful manuscript of my young friend Doring, 'On the Character and Nature of the Rose,' there is not even the smallest chapter on the fruit of rose as an apple of discord."*

It is hardly worth while to read every statement and counter statement in this quarrel, but we believe that Messrs. Booth, the nursery men, must have the best of it, as undoubtedly the excitement has enabled them to sell the greater part of their stock of this rose, as well as of many others approaching to it in character, to enable a comparison; while the publishers of Redouté's work on roses have certainly disposed of several copies to persons who have withstood the best newspaper puffs that ever were penned.

[There have been very many instances, in modern as well as ancient times, of parties being formed, and bitter feuds engendered among countrymen, neighbors, and former friends, for causes not more important, and even less understood, than those from which have originated the *rose factions* mentioned above. And most parties agree with those of the *roses* in another respect—that the few knaves who lead, on both sides, may gain by the feud, while the many fools who follow them, are sure to be losers.]

From the Horticultural Register.

ON THE VEGETABLE PRODUCTION OF INDIA RUBBER, AND ITS APPLICATION TO MANUFACTURES.

At the present time, when attention to this subject is so much awakened, we deem an account of it will be of some interest to our general readers, particularly as an entirely new and extraordinary use for it has been very recently discovered and patented in England.

The India rubber in the state it is imported into this country, is the concrete juice of the Hevea caoutchouc, or guianensis, a Euphorbiaceous plant which abounds in South America; it is also produced from the Apocyneous plants, as Urceola elastica, of Sumatra, Vahea Madagascariensis, Ficus elastica, of the East Indies; and from Artocarpeous ones, as Ficus indica, the Banyan tree also of the East Indies, Artocarpus incisa, the Bread fruit tree, from the West Indies, and from many trees in Africa. In fact, plants producing it grow in almost all countries in or near the tropics. The produce of these is sometimes equal to nearly

* The apple was placed by Decandolle in the Rosaceous family, from which it is now, however, properly separated. It is classed with others in a distinct order called Pomaceæ, from Poma, an apple. The figure of Nees Von Esenbeck, of the rose fruit being an apple of discord is therefore not so far wrong as may appear at first sight.

two-thirds the weight of the branch tapped, and when exhausted, but a few months' rest are required to replenish the vessels; the supply is therefore equal to almost any consumption, although no doubt exists that this will increase amazingly. A small quantity has been manufactured from the juice of a tree in the Glasgow botanic garden, and exposed to the public at an agricultural museum at Stirling in Scotland.

Mr. Nuttall observes that the juice of the Milkweed, Asclepias Syriaca, which grows plentifully in the vicinity of Boston, as well as of that of the Apocynum is convertible into a substance resembling gum elastic.

A patent has been very recently granted in England for the manufacture of an essential oil or liquid, by distilling India rubber at a given heat in close vessels made for that purpose; by redistillation it comes over pure and transparent. This oil has many singular characters. It is the lightest liquid known, being of less specific gravity than sulphuric ether, it is exceedingly volatile, yet the gas formed when it evaporates is the heaviest gas known, and may be poured out of one vessel into another like water, as was exhibited at a late lecture given on it, by Dr. Faraday in London. The rapid evaporation of it, produces intense cold; one minute and a quarter was sufficient to reduce the thermometer from 60° Fahrenheit to 10° below zero, by covering the bulb with muslin and blowing on it with a bellows, while this liquid was dropped on it.

On removing the muslin at about 10° above zero, in another experiment, the bulb was observed to be covered with a concrete substance resembling snow, termed by Dr. Faraday. Bicarburet of Hydrogen, supposed to have been previously discovered by M. Mitscherlich.

On mixing this produce of India rubber with cocoa-nut oil, which is known to be always hard at the usual temperature of the atmosphere, in the proportion of one-quarter of the former to three-quarters of the latter, the cocoa-nut oil is liquified and gives a most brilliant flame.

Mr. Beale has taken out a patent in England, for a new lamp to burn this mixture; one of them was exhibited at the before mentioned lecture, and surprised the audience by its peculiar brilliancy.

It mixes readily with oils used for painting, and evaporates so speedily that the paint dries within an hour after laying it on. As it is extremely cheap and does not in the least injure the most delicate colors, it is probable that it will be considerably used for this purpose.

One of its most important properties, however, is that of completely dissolving all the gum resins, particularly gum copal, without the assistance of heat, therefore the varnish may be prepared without the usual danger from fire. It is also a perfect solvent in cold, of India rubber itself, and when this is laid on any substance in its liquid state, the oil evaporates and leaves the India rubber without the slightest alteration of its character, fixed on the material.

Messrs. Enderby & Co. of Greenwich, near London, have established a manufactory of this substance on a large scale, and have sent an agent to South America for the purpose of procuring a constant supply—they have always about one hundred tons to operate on.

The principal object of their manufactory, is to saturate the fibres of the Phormium tenax or New Zealand flax, with this liquid previous to its being made into cables, thereby rendering it totally impervious to water, and protecting it altogether from the effects of damp and moisture.

It has been named Caoutchouchine from Caoutchouc, another name for India rubber—which it is supposed, if carefully managed on distillation, would give nearly weight for weight of this oil.

Being so recently discovered, its properties are of course by no means entirely developed, and much remains yet to be known on the subject. Dr. Faraday's lecture is represented to have been most interesting—he exhibited the juice of the India rubber in its fresh state and explained how it deposited the article of commerce—he entered also into a chemical analysis of it, the repetition of which here would be trespassing too far on our horticultural readers.

From the Genesee Farmer.

ASHES AS MANURE.

Farmers who now have ashes on hand, will find it profitable to apply it as a top dressing to their corn, instead of selling it at the asheries. An application of ashes to this crop will not unfrequently cause an increase of more than five times the value of the ashes at the price they are commonly sold. Ashes which have been kept perfectly dry and uninjured are far preferable to leached, though the latter is very valuable. When it is applied to corn, one gill of that which is fresh or unmoistened will be enough; if leached, half a shovel full will not be too much. It is recommended that when unleached ashes is appled, it be placed on the surface round each hill so as not to touch the plants, as it might otherwise injure them by its causticity.

LEGAL RESPONSIBILITY OF POSTMASTERS TO PUBLISHERS FOR A VERY COMMON NEGLECT OF THEIR DUTY.

"The proprietor of this paper" says the Philadelphia Times, "last week, recovered judgement against a postmaster for a paper not taken from his office, of which he neglected to inform him. All postmasters who do so, render themselves liable, and ought to be held accountable."

We earnestly wish that every *careless* postmaster in the United States, and especially some of those to whose offices the Farmers' Register is sent, would read and profit by this warning. With many of these officers the most culpable neglect of their sworn duty in this respect, (if not worse than neglect,) is frequent. We have suffered by it, in common with most of our editorial brethren, by some very long continued and most gross offences of this kind—and if no other redress can be obtained, we shall try whether the law will afford it in Virginia, as well as in Pennsylvania. If publishers generally would adopt such a course, they would check much of the disposition to indulge in gross neglect, if not in petty pilfering.

From the New York Farmer.

BROOM CORN.

The cultivation of broom corn is carried on to a very great extent on some of the alluvial lands on the Connecticut river, and in small patches in many of the interior towns. The towns of Hadley and Hatfield raise large quantities, which are manufactured into brooms, and distributed throughout the country. The seed is considered of about two-thirds of the value of oats, and, mixed with corn, makes an excellent provender for the fattening either of swine or neat cattle. The return of seed is somewhat precarious; but often it is abundant, and will more than pay the whole expense of cultivation and preparing the crop for the market. I have known a case in which 150 bushels of good seed have been obtained from an acre; and I have been assured, on good authority, of a still larger yield, though this is not frequently to be expected. One thousand pounds of broom to an acre is a very good crop. It will pay well for manuring and good culture. No crop is more beautiful than the standing corn when in perfection. It frequently attains a height of 12 to 15 feet. The stalks of the plant are very long and hard, and, therefore, rather difficult to load upon a cart. They are considered as of no value but for manure. The usual practice is to table the corn, that is, to cut off the top, or tassel the broom, as it is called, about two feet from the top, and bending the stalks of two rows together, lay it down until it is seasoned and fit to be carried in. The remainder of the stalks are then burnt in the spring in the field, and some little advantage is derived from the ashes. A much better way, it is thought, is, after gathering the crop, to cut the stalks and lay them lengthwise in the rows, and plough them immediately under. They will become entirely decomposed by spring. A still better mode is to carry them into the cattle and sheep yards, where they become incorporated with the manure, and make a valuable addition to the compost heap.

The seed is planted in rows, wide enough apart for the plough to pass conveniently between them, and dropped in hills about eighteen inches from each other. Four or five stalks are considered sufficient to remain in a hill—more are sometimes allowed. The cultivation and manuring is more than for Indian corn. It may be manured in the hill or by spreading, or in both ways, as you have the means of high cultivation, which this plant will bear. The stalks are not eaten by cattle, nor even browsed by them; but I am not certain that the leaves would not furnish a good feed for young stock, if stripped early, when tender, and well cured, as the Indian corn blades are cured at the south. What would be the effect of such mutilation upon the crop itself, and whether it would compensate for the labor, are inquiries which I am not able to answer, and in respect to which I cannot learn that any experiments have been made. It is an important subject for experiment. As it is at present managed, the plant returns little to the ground compared with Indian corn; and the Hadley and Hatfield farmers are obliged to connect with it the fattening of beef to a considerable extent, to furnish manure for their broom corn.

It is deemed a good crop when the broom commands five cents per lb. The price has heretofore been subject to great fluctuations. At one time it was the custom for every farmer to make up his own brooms, and then to go and sell them where he could. This was bad for all parties. It brought too many competitors into the market; and often unduly depressed the price, and the buyers were often obliged to put up with an inferior article. Now the manufacturing and the growing of the broom are in different hands; and the farmer, as soon as his broom is ready for the market, finds a purchaser at a steady price; and the manufacturer feels that his reputation, and consequently his success, are concerned in the quality of the article which he furnishes.

It is a little remarkable, that notwithstanding the extent and importance of this product, for one manufacturer within a few miles of me makes several hundred thousands of brooms a year, that in no book of agriculture in my possession can I find any account of the cultivation of this plant, not even in that excellent New England work, "*The Complete Farmer.*" The Shakers for a long time almost monopolized the raising of the plant and the manufacture of brooms; and their brooms, which, like the other manufactures of this industrious community, were always of a superior quality, usually commanded a high price, generally 42 cents or more. Corn brooms are now frequently sold from eight to twenty-five cents; but many of them are like Pindar's razors, "made to sell." The Shakers, however, maintain the quality of their manufacture. The handles, in an unfinished state, are furnished for a cent a piece; the wiring and the tying on are usually done by the hundred. The scraping the seed from the brush is an unpleasant business, and often very injurious to the eyes. The manufacture, where it has been carried on extensively and with ample capital, has yielded encouraging profits.

An intelligent and enterprising farmer in my neighborhood, who last year cultivated three acres and one-half of broom corn in our alluvial meadows, has been kind enough to furnish me a detailed account of the expense of cultivating an acre, which may be relied on for its exactness, but in which the rate of labor is probably over-estimated by the day. His broom was sold in the autumn at eight and one half cents per lb. It readily commands this spring $12\frac{1}{2}$ cents; had he fortunately retained his broom until this time, the profits would have been greatly enhanced, while the expenses would, of course, have remained the same.

Account of the expenses of cultivating an acre of broom corn in Deerfield meadows, in the year 1834, by Mr. Alvah Hawkes:

One ploughing, 12th May,	$1.25
Holeing out, one-third of a day's work,	34
Ten loads of manure, at 75 cents,	7.50
Putting manure in the hill,	2.00
Planting, one day's work,	1.00
Seed, four quarts, at 75 cents per bushel,	10
Hoeing, first time $3\frac{1}{2}$ days,	3.50
do. 2d do. 3 do.	3.00
do. 3d do. $2\frac{1}{2}$ do.	2.50
Horse and boy to plough for the season,	1.00
Tabling and cutting, four days,	4.00
Gathering, carting, and packing away,	2.50
	$28.68

The expense of cultivating one acre is $28.68

cents, the labor being rated at one dollar per day, which is more than the actual cost, as I hired my laborers by the month, at from six to ten dollars per month. The yield was at the rate of 991 pounds to the acre. Had all my ground been fully stocked, it would have exceeded ten hundred pounds per acre.

The expense of scraping the brush for the seed was thirty-three cents per hundred pounds. The brush was sold at $8\frac{1}{2}$ cents per pound. The crop of seed was light and poor; fifty bushels to three acres, worth $16\frac{2}{3}$ cents per bushel, or $8.33 to an acre.

Summary expense of cultivation of one acre as above,		$28.68
Scraping 1000 pounds,		3.30
Board of man five days,		1.07
Rent of land, say $16 per acre,		16.00
		$49.05
Sale of brush, 1000 lbs. at $8\frac{1}{2}$ cents,	85.00	
Seed upon one acre,	8.33	
		93.33
Net profit on one acre,		$44.28

The sale of the brush at $12\frac{1}{2}$ cents per pound, the present price, would have enhanced the profits forty dollars, and made them $84.28. This is very remarkable, and certainly affords ample encouragement to labor. That it can be often done is not to be expected; and yet there is nothing extraordinary in the process. The uncertainty of the seasons is something, and the fluctuations in the market prices of broom are great. The amount of crop, though large, was not more than can usually be commanded by good and generous cultivation. Many of our lands, besides the alluvial meadows, are capable of producing good crops; and the great yield of 150 bushels of seed to the acre mentioned above, with broom, of course, in proportion, was produced in one of the most rough and rocky towns in the commonwealth, and on land which owed every thing to good management. I hope the length of these details may be excused.

H. C.

Meadowbanks, (Mass.) May 7th, 1835.

From the Southern Agriculturist.

ON THE DISEASES OF TREES, AND METHODS OF CURE.

When it is observed of a tree, that it does not shoot forth, we are certain that it is either punctured to the liber or white bark, or that it is deficient in nourishment from the poverty of the earth, in which it is planted, that will in time prove its destruction. The remedy is to lay bare the roots in the month of November, for three feet around the tree, and put in three or four baskets of well rotted cow manure; throw upon this three or four buckets of water to force the manure amongst the roots, after which fill up the hole with the same earth that was taken out of it: the roots becoming refreshed, throw out new fibres, and the year after the tree will be seen shooting forth its green foliage again. If the summer is very dry you must throw two buckets of water around it from time to time. The winter following in trimming the trees, you must not leave as many branches as on those that have always been in good health. Trees of every description are cured in this manner.

Bad soil.—Fruit trees accommodate themselves more to warm light earth than to that which is cold and wet.

Diseased roots.—Frequently a tree, all of a sudden, after have thriven many years, will become weak and languid: this arises from the roots becoming rotten from having been planted too deep, from the many fibres, from humidity or otherwise. This is easily remedied by laying bare the roots in autumn, and cutting off such as are decayed, up to the sound wood.

Exhausted earth.—If the tree languishes in its sound roots, the malady arises from the earth being too much exhausted. To reanimate it, remove the exhausted earth and replace it with new; afterwards throw around the foot of the tree two good baskets of cow manure, if the earth is warm, or that of the horse if it is cold, and when the time arrives to trim it, cut out the old wood. If it does not shoot forth well the succeeding year, it ought then to be dug up and thrown away.

To regenerate old trees.—When you have in your garden a very old tree, whose branches on the right and left indicate dying, you may calculate the cause to be in the roots: it wants nourishment, and the earth about its feet is too old, exhausted and dry. To give it again health and vigor, lay bare the roots in the month of November, for four feet square all around them so as not to injure them; afterwards throw five or six baskets of well rotted cow manure above the roots, the fall and winter rains will decompose it; if the winter is dry, you must water it, in order that the liquor of the manure may become a kind of pus to nourish the roots; the sap will begin to flow, and the earth and tree revive. In the month of February, cut the old branches to the body of the tree, covering the wound so as to prevent either rain or the sun from doing any injury. After the first year, the branches will be three feet; and, if it is a tree which ought to be trimmed, the winter after trim the branches a foot long. This manner of resuscitating all kinds of trees is excellent.

Trees diseased on one side only.—If a tree is diseased on one side and vigorous on the other, lay the roots entirely bare, remove the diseased part, and cut the larger roots in order to make the tree equal, and the circulation of the sap more general; put new earth above the roots, even if they should not be unhealthy, and two or three baskets of manure as above.

When you trim this tree, leave the vigorous side long, and you must leave all the fruit branches, even the weakest, so as to draw the sap: trim very close the diseased side; cut off all useless branches, and leave a few fruit branches.

Yellow leaves.—This disease arises often from the same cause as that of the disease last spoken of, that is to say, exhausted earth. In such case administer new earth mixed with manure reduced nearly to that of common earth; or, without entirely uncovering the roots, with ashes and soot, these materials are very good for light earths. When the ground is cold, pigeon dung is very good, particularly where it has been in a heap for two years, to ameliorate its strong heat; spread it an inch deep about the foot of the tree, and in the month of March following bury it. For the want of this dung, you must take away the old earth from around the tree and replace it with new, mixed with fine well rotted horse manure. If the yellowness arises from the earth being damp, take horse-dung mixed with water, so as to form a kind of pap, make a trench around the foot of the tree, pour in the mixture, cover it, and let it thus remain: it will reanimate it. If the yellow leaves arise from a contrary cause, that is, from the soil being too light and dry, you must as soon as the month of November arrives uncover the roots, and put above them the scrapings or settlings of a pool, well drained, worn out, and exhausted street mud; hog-dung or other similar manure: these simple and easy means will resuscitate them.

A tree often becomes yellow from having given too much fruit, and exhausting its substance. In this case you must pull off a part of the fruit and apply fresh nourishment to the roots.

When a tree appears to languish, make a circle around the foot of it, in which you must put any convenient manure; in trimming it, cut off all superfluous wood, and after having filled up the hole in which you have put the manure, leave nature to act, and she will resuscitate it soon. In digging around the tree, keep off at from two to four feet distance, observing as you approach the tree to dig carefully around the mound in which the roots are formed.

Sterility.—Open the earth about the foot of the tree, cut off the extremities of the large roots, shorten those that are too long or far off, and all the small ones near the trunk; throw good new earth upon them and cover them up.

Means to produce fruit from trees which flourish well, but whose fruit becomes blighted almost every year.—There are some trees which are charming to the sight when in blossom, but which retain none of their fruit: in this case, at least six buckets of water thrown around them when in full bloom, will answer a good purpose. If you have not so much water, you may refreshen the tree by sprinkling the buds. When the fall of the blossoms is in too great an abundance, bleed the tree or prune the roots.

Inertness of the sap.—In very cold and dry summers in which there is not much rain, it happens that the sap ceases to flow by degrees. You will then see a great portion of the fruit, particularly peaches, which have the most need of a large stock of sap to acquire maturity, fall or prove abortive. The only remedy in this case is to open around the foot of the tree, and to throw in a bucket of water to open the pores and revive the sap, which will prove well that watering and vigilance are necessary in gardening.

When the spring is dry and cold, it happens often that a peach tree does not shed its blossoms, the flower attaching itself to the small nut of the peach, dries it up and makes it fall; to remedy this, you must bare the roots and throw in buckets of water, and when it is dried up, cover them again with earth, and continue watering them every week during the months of March and April, until you find the fruit safe and well grown; this raises the sap and saves the fruit; it is good to water freely peach and apricot trees during the great heat of summer, and above all, when the fruit is approaching to maturity. When the fruit is well grown, the tree must be thinned of those that are superabundant, which not only makes the fruit grow larger but better, it also preserves the vigor of the tree, which would become ruined in two or three years, if you do not proportion the fruit to the strength of the tree. Peaches, nectarines, and apricots, must be thinned in May. Only a few fruit must be suffered to remain on the weak branches.

When the heat is great and a continual drought, at the end of July, and during the month of August, it is good to throw around the foot of the tree, and particularly the peach, a bucket or half bucket of water, so as to rouse the sap and prevent the fruit from falling half ripe. When you observe the tree languish and the fruit advance very slowly and fall in great numbers, you may be sure it is in the sap: you must then put water to the foot of the tree, for which purpose you must make a trench around it at a short distance, so that the water may be better held, cover the earth with leaves or straw, and throw water on it, so as to enable the earth to preserve its freshness.

To give fruit a fine color, about the end of June clip with a scissors those leaves that surround the fruit, and when they have grown nearly to their size, remove all their leaves from around them, so that the dew, rain and sun may penetrate, paying attention to the soil, the weather, and the strength of the fruit, for delicate fruit becomes scorched if laid bare too soon, and if too late will remain without color and taste. Peaches and apricots should be laid bare only fifteen days previous to their being ripe, otherwise the fruit would become defective and imperfect about the stone. By jetting water with a syringe upon fruit exposed to the sun two or three times a day, you will give it a peculiar and curious color, but at the same time impair the quality.

When the severity of the heat occasions the fruit to fall, instead of watering, dig round the roots two inches deep, which fill up with the ashes of wood, and to prevent the wind from blowing it away, cover this ashes with earth.

Peaches and apricot trees are liable to what is termed the blight, which is an injury that shows itself by the leaves becoming crimped, shrivelled, dull and yellow, they fall about the first rain; you have nothing to do but first to remove all the blighted leaves, so that the new foliage of the succeeding spring by force of the sap of those which have been blighted, come quicker.

To remove gum you must with a proper instrument cut down to the inner part of the tree, and cover the wound with dry earth tied on with a cloth.

This is the general method of treating diseased trees in France, which from similarity of climate with that of this country, will apply here. Many persons believe it to be only necessary to plant a tree, and that nature will do all the rest. It is true, we must depend upon nature for the success of our endeavors; but we must recollect that the fruit trees we cultivate, are not indigenous to this climate, and that our want of skill and judgement in planting and nourishing them, may embarrass the operations of nature in bringing the fruit to perfection. It becomes necessary, therefore, to ensure success, that we should aid nature in her operations, by removing all obstructions to her efforts, and furnishing the proper attention and nourishment for the prosperity of the tree. In order to effect this, observation and experiments are necessary; and ordinary care and attention to the method prescribed above, will be sufficient to accomplish our purpose.

How much, then, is to be deprecated that want of zeal, which is so clearly manifested in this section of the country in relation to the cultivation and care of fruit trees. Providence has peculiarly blessed us with the means of indulging in most of the luxuries enjoyed by other sections of the globe, but our apathy appears to have created a total disregard to her munificent blessings in this respect. There is no spot on earth where most of the stone fruit of other climes, could be cultivated in more perfection than in this State. The diversity of soil produces diversity of fruit, and although, on Charleston Neck, peaches and nectarines are destroyed by various insects, yet, all kinds of plums and cherries may be raised in great perfection: some of the latter raised there by Mr. Michel, are equal in every respect to any ever produced in a more northern climate. Cultivators instead of importing and increasing the fine plums of France, appear to be satisfied with the miserable trash that grow unheeded and uncared for in thickets. This negligence is reprehensible and ought to be corrected.

A FRENCHMAN.

From the Charleston Mercury.

WHITTEMORE'S IMPROVED COTTON GIN.

We had the pleasure the other day of examining the gin described in Mr. Whittemore's advertisement, and observing its mode of operation; and we would advise every Sea Island planter in the city to go and do so also. The advertisement falls short of justice to the simplicity and completeness of the mechanism, which is admirable throughout. The cotton is ginned without breaking the seed or injuring the staple, the rollers being preserved from being heated by friction rollers. The moving power is applied somewhat on the principle of the treadmill, the horse or ox being placed upon a revolving floor which moves from the weight of the animal, and obliges him to keep his feet in motion. By this means the motive power is communicated by the use of the endless chain to the cylinder above, to which the wheels of the gins are similarly attached.

One of the gins is made to work either by the treadle, or by the machinery; and it is very far superior in every respect to the common foot gin. As far as we are judges, it is altogether the greatest improvement on the Sea Island cotton gin that we have seen. The moving power may be used with ease for other purposes, such as to work the thrashing machine, for which purpose it is in extensive use by the northern farmers.

The advantages of these gins, are the following:—greater durability—less liability to get out of order—getting out more cotton in a shorter time, and cleaner, than any previous invention. The trifling expense, and great ease with which they are propelled; the very small space occupied by the whole machinery; the prevention of all heat from friction, the cotton does not "backlash" or wind and entangle itself round the rollers; all the parts subject to wear are of cast steel: they can be worked by the treadle or by horse power, at pleasure; the rollers can be taken out and replaced in one gin, without interrupting the works of the others, and the ginner need not be detained more than two minutes while it is doing.

But the planter need but visit it to be convinced of its important advantages over the gins in common use on our plantations.

ON THE SOILS AND AGRICULTURAL ADVANTAGES OF FLORIDA.—No. I.

To the Editor of the Farmers' Register.

Plantation Wascissa, Florida, 6th June, 1835.

Though unknown to you, I shall not apologise for this intrusion upon your attention. The spirit of your widely circulating Register, solicits the contributions of all farmers, and though a very humble one, I do not hesitate to exercise this privilege of my vocation. Another ambition also incites me to write publicly—it is, to promulgate throughout the exhausted districts of the more northern and densely populated states, the increasing value and prosperity, in lands and health, of this territory; and to counteract, by the simple statements of personal observation, the influence of exaggerated reports, which have for some years so materially checked the advancement of Florida, and turned from her the flow of northern emigration. Abler pens would doubtless accomplish this object with more elegance of diction, as well as with more successful results; but in their indolence, truth, though uttered with simplicity, may prove sufficiently interesting, to pardon the officiousness of my egotism.

I have taken with increased gratification the last two volumes of your valuable periodical, and faultless as it is, I would suggest with deference, your devoting more of its columns to agricultural practices and improvements, adapted to the "*far south.*" We are here extremely limited in book farming, and generally ignorant of "making two blades of grass grow where one grew before"—and conceiving that with you lay the ability of instruction, I have regretted that so much of your publication could not be practically applied to our new lands, and *pioneering* systems.

Some two years since I came first to Florida, after a residence of some years, as a sugar planter, in the British West Indies; from whence I was forced, with a sacrifice of property and prospects, by the mad abolition act of the infatuated English government. My object in selecting Florida as a residence, was to establish, under a secure and honest constitution, a sugar growing estate: and before I conclude these letters, (to be only continued under your approbation,) I shall express my opinion and experience as to its practicability. At present, I shall endeavor to describe the character of the various soils, peculiar to the different sections of this valuable and little known peninsula, which I have visited—commencing at the Atlantic shore, and proceeding westward.

The territory of Florida is divided into four grand districts, each of which are subdivided into counties—as it is of the "districts" I shall speak, I will briefly detail their respective limits, and appellations. The eastern district, commonly called

East Florida, extends from the Atlantic, westward, to the Suwanee River, and as far south as the parellel of 27° latitude. The middle district, known as Middle Florida, is comprised between the Suwanee and Apalachicola Rivers. The western district, or West Florida, from Apalachicola to the Perdido River—and the southern district includes the extremity of the peninsula below twenty-seven degrees, and the fortifications on Key West. The distinctions of arable soil to be found in the eastern section, are between the high hammocks or uplands, and the swamps or low bottoms. The former are chiefly composed of a gray vegetable mould, mixed with white sand, and based on beds of indurated or stone marl, in such abundance, that it rises in layers or shelves on the surface. This excess of lime I hold to be the destructive quality of these lands; for I conceive, that though marl in all its varieties is, under proper proportions, an auxiliary to soil, it is, when in excess, and solely uniting with silicious land, detrimental to production, and extremely injurious. Clay, or other absorbent, is essential for decomposing and imbibing the generic heat of calcareous matter; without it, lime, in excess, "consumes the meat it feeds on;" and by its continued thirst, creates the destructive effects of drought. The growth on these lands in the east, is indicative of this fact—being a stinted production of dwarf or scrub oak, and the steril palmetto. They are notwithstanding generally cultivated, and yield cotton productively for three or four years, or as long as the vegetable moisture exists; but at the expiration of that time, they become dry, glazed, volatile, and unprofitable. Corn cannot be grown profitably at any time; and sugar being of the same genus, is difficult of culture. The richness, however, of the bottoms or swamp lands in this section, more than compensates for any deficiency in the uplands. They extend variously from a half to three miles from the margin of the creeks and rivers, lying perfectly level, and covered with a dense growth of forest trees, interlaced with innumerable grape and other vines, and in some instances, breast high with luxuriant and never dying grass. They are purely alluvial, and formed solely on viscous soluble marl, by the gradual deposite of vegetable matter held in the overflowing waters. They would, of course, require ditching and drainage to be fit for cultivation, and this is most feasible: and once accomplished, would forever secure an inexhaustible and inestimable soil. The owners of these bottoms are fully aware of their value, but the want of labor, and the "thousand and one" difficulties to be executed on a new settlement, have compelled them to cultivate, as yet, almost entirely the more easily cleared uplands. Some have, however, succeeded in bringing the swamps into culture already, and the luxuriance of the sugar cane crop upon them, has more than justified their expectations—2000 lbs. and upwards, per acre, of muscovado sugar has been averaged from a thirty acre field. I may respectfully mention General Hernandez, (one of the few remaining Spanish grantees now amongst us,) who has with great perseverance and success, overcome the laborious difficulties of clearing and draining new land; and has now under culture, upwards of 200 acres of these swamp lands, constituting by far the most valuable plantation, as respects soil, in Florida, and equally as healthy as any other to his slaves. I may convey some idea of the comparative value of these redeemed marshes, in stating that a late appraisement made over Gen. Hernandez's estate for banking purposes, estimated his cleared swamp at $80 per acre, while similar appraisements elsewhere of the finest upland, has only reached $15 per acre. I express myself strongly respecting these swamp lands, on the conviction that they must ultimately become the chief sugar growing lands of these states. They lie immediately on the sea board, between latitude 29 degrees, and as far south as the surveys of the peninsula have gone. They have many advantages over the Mississippi bottom lands, as regards climate, health, and proximity to the northern markets, and nothing is wanting to exhibit their greater value, save capital and labor. Now that there is a probability almost reaching a certainty, that the supply of sugar will continue for some years less than the demand, it would be well for the capitalists of your state to turn their attention to its manufacture—and I speak from personal examination in saying that the swamp lands of East Florida, and especially those lying on the branches of the Matanza and Halifax Rivers, are superior in strength and character for the production of sugar, to the most valued lands of the West India Islands—only excepting the ashy loam of St. Kitts. The little success which has as yet attended the planters of the east on these swamps, is entirely owing to a misapplication both of money and labor: and must not be taken as an evidence at all of the land, except to show that had the lands been *bad*, under the same want of practical husbandry, the cultivators would ere this have become beggars.

Extensive tracts of land are yet in the market, comprising large proportions of these "bottoms;" though the late organization of an "Union Bank," with its issue upon landed security, has enhanced their value. The health of such low grounds beneath a tropical sun, cannot be justly eulogised, although with the exception of the "dog days," they may be denominated safe and agreeable residences; and during those trying days, St. Augustine, so justly famed as the Montpelier of America, affords a most fascinating retreat, with

Its sweet orange groves—and evergreen bowers—
And the atmosphere loaded with the breath of their flowers!

It has been, sir, a source of much regret, that limited means have compelled me to forego a settlement on these inexhaustible mines: but alas! like Shakspeare's apothecary, "My poverty but not my will consents." It has been a serious obstacle to the advancement of our sugar plantations that most of our planters have commenced them without adequate resources. It may be advantageous and desirable that a cotton farmer should not have too much wealth: the operations of his estate can be successfully executed without any expensive machinery, or large outlay of dead capital. Not so, however, with a sugar plantation—the salvation of its crop, and its profitable manufacture, are dependant, in *this climate* of variable and *limited* autumn, upon effective and sufficient machines—all of which cost much in material, in construction, and most in erection and application. Yet how few calculate this necessary and preparatory outlay! But of this, more anon. I must conclude this *essay* upon your time and space, lest besides its many faults, its length should add to render it unworthy a "second reading." I trust that it may be acceptable: if so, I promise myself the pleasure of again writing for a future publication, and to continue these letters upon the other sections of Florida which I have visited, until, Mr. Editor, my observations, or *your* indulgence shall become exhausted.

FARQ. MACRAE.

[It would be a superfluous declaration on our part, that further communications from the writer above, will be acceptable and gratifying, but for his expression of doubt on that head. His continuation of this particular subject is requested as early as it can be furnished—and future communications on any other subjects, as the writer's leisure may permit.

We share with our correspondent the regret that more space in this journal has not been given to the agriculture of "the far south," and to the management and lands of the newly settled country. But the fault is not *ours*—and the acknowledged deficiency will soon be filled up, if only a few more of the intelligent cultivators of those regions, were, like our correspondent, sensible of the general want of such information, and would come forward and communicate their own respective acquisitions. Such communications would serve as seed to produce many others in due time—and the harvest of gain would be sufficiently abundant to reward all who aided in the labor, whether they commenced at the first or the "eleventh hour."

But while admitting the alleged deficiency of articles especially relating to the agriculture of the far south, and still more of newly settled lands, it may be justly claimed that we have paid far more attention to those regions than their cultivators have to our work, or to the promoting of their own interests by making proper use of it. Compared to the small amount of the subscriptions, and of the more valued written contributions to the Farmers' Register from the southern cultivators and pioneers, at least as much of its contents have been devoted to their peculiar interests, as to those of any other part of our country. It is to be hoped that more correct views are slowly extending—and that southern planters, both on old and new lands, will know that both their pecuniary and political interests, may be better sustained by aiding the hitherto weak, but zealous efforts of this journal.]

From the Richmond Compiler.

HYDRODYNAMIC RAILWAY, OR THE APPLICATION OF THE POWER OF RIVERS TO THE RAPID AND CHEAP TRANSPORTATION OF PRODUCE AND MERCHANDIZE.

It has long been with me a matter of doubt, whether the water used in the lockage of canals was not in many cases an injudicious application of a valuable power, as in the case of a canal located along the valley of a great river having considerable fall in its bed, like that of the river James, which has 1222 feet fall from the Covington to tide-water, or about 4.74 feet per mile, rendering at least one lock necessary for every two-miles in the average.

On investigating the subject, I find that the water power of the river is of itself equal to the transportation of a greater quantity of tonnage than can be passed through the largest canal, and this too with the astonishing rapidity peculiar to rail roads.

I will therefore lay before you, in as succinct a manner as possible, this new, though simple, deduction of science.

The locks of the Chesapeake and Ohio Canal are 100 feet long, 15 wide, and, say we take one of the most approved lift, 8 feet, the "prism of lift" will then contain 12,000 cubic feet of water, which will weigh 750,000 pounds. Every time the lock is emptied, this quantity is transferred from a superior to an inferior level. If the valves are opened simultaneously, I am informed that the lock can be filled and emptied in little more than two minutes; but say that it takes three. Now, this water is power, and if it were applied to a properly constructed "breast wheel," or where the fall of water is greater, to a "pitchback," we should have four-fifths of it available to set any machinery we think proper in motion. Let it be applied to an endless chain or rope, passing over suitable rollers along the line of a railway, after the manner of the stationary system of steam engines, we shall have a water power railway, entirely free from the objections that can fairly be urged to the stationary steam engines, of the necessity of keeping up the fire and steam, &c.

When the stations are two and a half miles apart, one-twentieth of the power, according to Tredgold, will be expended in moving the chains; but I will allow a tenth of the power to effect this object on two mile stations, the chain being worked but for one mile.

We have then the four-fifths of 750,000 pounds, (the one-fifth being lost in the application to the water wheels) equal, 600,000 pounds, which, falling 8 feet in three minutes, is equal to 1818 pounds moved half a mile in the same time; which is at the rate of 10 miles an hour. Deducting from this the one-tenth, as that part lost in moving the chain, leaves 1637 pounds. And as 10 pounds are equal to the transportation of a ton, with the commonest railway wagons, it follows that the above power is equal to the transportation of 163.7 tons over half a mile of the road, while a boat would be passing through the lock of the canal; or it will transport 81.8 tons over a mile of the road in the same time, which is at the rate of twenty miles an hour!

But the maximum rate of transportation on canals is $2\frac{1}{2}$ miles an hour, and as the mass moved is inversely to the velocity, we shall at this rate be able to transport 654 tons.

The water used would be at the rate of 66.6 feet per second. James River, even at Covington, in a dry season, yielded nearly three times this quantity, as appears from the Report* of Mr. Crozet, who measured Jackson's River and Dunlop's Creek in August and September, 1826. The mean of the results obtained by this engineer is 177.6 cubic feet per second, or 10,656 feet per minute; and we have this quantity with 7.11 feet fall per mile, the average down to Pattonsburg; before reaching which, however, the volume of water is more than double; and as we descend the river,

* 5 Vol. Board of Public Works, page 108.

although we have less fall per mile, we have at least six times the quantity of water to compensate for it; and the fall is still about 3½ feet per mile.

The heavier trade being descending, will add to the effect of this power; but disregarding this favorable circumstance omitting the decimals in the fall per mile, and taking the minimum quantity, we have 10,656 cubic feet of water equal in weight to 666,000 pounds, which if permitted, will of course fall the 7 feet in a minute, and is therefore equal to 4,662,000 pounds falling one foot. Deducting one-fifth for loss in application, leaves 3,729,600 pounds. Now the load we can transport will depend on the velocity at which we would travel—say that it shall be 10 miles an hour, which is 880 feet per minute.

Dividing 3,729,600 by 880, the quotient is 4,238 pounds, moving with the velocity of 10 miles an hour!

From 4,238 deduct the one-tenth part, for that lost on mile stations, in moving the chain, or rope; and dividing the remainder by 10 for the friction per ton of the carriages, and we have 381.5 tons transported at the rapid rate of 10 miles an hour!

And as each and every mile furnishes its own moving power, it follows that it is equivalent to keeping this quantity in motion on each mile throughout the line at the same time. And as the distance from Richmond to Covington is 257½ miles, this may amount to the enormous quantity of 98,236 tons; or to the transit and delivery of 3,815 tons hourly!

Having thus demonstrated the amplitude of this moving power, to an extent probably far beyond any demand we shall be able to make on it—which will be better understood by the general reader from the fact, that but 17 hours would be equal to the transportation of a greater quantity of tonnage than passed over the whole Baltimore and Ohio Rail Road in a year ending 30th September, 1833—it now remains to show that it can be employed at a reasonable expense.

The expense of erecting works for hydrodynamic transportation will depend on their scale, or magnitude, and on the greater or less permanent character of the materials used in their construction; also, on the extent to which we would employ the motive power. With regard to the latter, however, it should be observed, that we obtain it so cheaply, and in such excess, as to obviate, to a great extent, the necessity of expensive grading. This adaptation of fixed power to an undulating surface, of any degree of slope renders it peculiarly applicable to mountain localities, as by its means we can cross the bends of the river, thus shortening the distance, while a canal, or even an ordinary rail road for locomotives, should be conducted round them.

Another important advantage derived from the employment of this cheap power, is that we can substitute, for the iron rail, a broad granite tramway similar to that extending from London to the West India Docks; which, although it will cost more per mile in the first instance, yet it will have great permanency to compensate for this. But the most important advantage to be derived from the granite tramway, is, that any man may bring his own farm wagon, and, leaving his horses behind him be drawn to market at a rate of 10 or 20 miles an hour, which would be in less time than would be spent in passing the locks of a canal: thus freeing the work entirely from the odious charge of monopoly brought against rail roads.

To form an estimate of the cost, it will be necessary to suppose the works adapted to some definite amount of trade. Say that it shall be to the delivery of 100 tons per hour, or to the transportation of 50 tons at a time, at the rate of 10 miles an hour.

For this purpose I will suppose it necessary to erect a dam at every four miles; and that they may be built in the most substantial manner of stone masonry, I will estimate them at $10,000 each; the average width of the river up to the Blue Ridge is 699 feet; above the Ridge, it will only be 275 feet. For water wheels of the best and most durable construction, say $3000.

Thus we have 13,000, which, divided by 4 miles, gives $3250 per mile, as the cost of the moving power.

Estimate of the Expense.

Motive power, or proportional cost of dams per mile, - - -	$3,250
Ropes, a double line per mile, -	1,800
Rope rollers, put up, - -	850
*A broad granite, or marble tramway, double track, - - -	8,000
Grading and bridging per mile, say,	2,000
	$15,900
Add 10 per ct. for superintendence,	1,590
	$17,490

High and unfavorable as the above estimate is, yet the whole cost of the moving power, including dams, water wheels, ropes, and rollers, will be much less per mile than such locks as those of the Chesapeake and Ohio Canal, which cost, as I am credibly informed, $1500 the foot lift.

I have estimated for ropes, as they are in more general use than chains; and the above will be the cost of the newly invented rope, saturated with India rubber, expressly for this purpose; which is said to increase its strength as well as its durability.

When the stations or water wheels are placed 4 miles apart, each wheel would have to work 2 miles of the road at a time; but did the trade require it, double, or probably treble the foregoing tonnage could be delivered by erecting an additional water wheel at each station.

The following is the estimate of the amount of power to work the 4 mile stations, which those conversant with the subject will perceive to be very ample.

Friction and resistance of two miles of rope, - - - - -	600 lbs.
Ordinary friction of 50 tons of carriages and goods, 10 lbs. - - -	500 do.
Allowance for occasional gravity, at 20 lbs. per ton, - - -	1000 do.
Power allowed at the rate of ten miles an hour. - - - -	2100

* Wood and iron rail tracks, like those on the Petersburg Rail Road, could be laid in a double track for 6000 dollars a mile. They would last much longer than when locomotives are used.

2100 pounds moved 880 feet in a minute, is equal to 1,848,000 pounds moved one foot; which is equal to 154,000 pounds falling 12 feet in the same time, which is, also, equal in weight to 2464 cubic feet of water. To which add one-fourth, for loss in application, and we have 3080 feet per minute, or rather more than 51 feet per second.

For the sake of conveying an idea of the probable cost on a large scale, I have supposed isolated dams to be used at regular distances, but the engineer will of course adapt his works to suit particular localities, sometimes preferring a continuous canal, substituting water-wheels in place of locks, and thus discharging the water, as it is used, into the next consecutive reach below. Or where great length of level occurs, the wheels may be made to discharge their water into the river, to be again taken out of the next dam.

On canals already constructed, where they have considerable lockage, and plenty of water, it is obvious that the trackage may be effected by the foregoing means; that is, by erecting a water-wheel along side of a lock, and extending a chain down the margin of the canal on the one side, which would be returned up the other.

And as they no longer need the tow-path, they may lay a light rail track, on which passenger cars may be drawn by the same power at any required velocity.

But in many cases, where thay have not a superfluity of water, they had better substitute water wheels for their lock gates, widen their tow-path, and lay down a railway.

In conclusion, I invite investigation by men of science, as it is certainly a subject of great importance to the country, now so extensive engaged in works of internal improvement.

JAS. HERRON,
Civil Engineer.

Richmond, Va., May 26, 1835.

SPAYED COWS.

[While the foregoing sheet containing the French article on this subject was printing off, we discovered that the piece therein referred to was in one of the volumes of our library. It is here given entire. The piece stands in the American Farmer of 1831, as copied from the New England Farmer, probably of a date not much earlier, but not stated. If this piece had not escaped our memory its being presented would have rendered unnecessary the remarks in a proceeding part of this No.]

From the New England Farmer.

Mr. Fessenden.—Some years since, I passed a summer at Natchez and put up at the Hotel then kept by Mr. Thomas Winn. During the time that I was there, I noticed two remarkably fine cows, which were kept constantly in the stable, the servant who had charge of the horses, feeding them regularly, three times a day, with *green Guinea grass* cut with a sickle.

These cows had so often attracked my attention, on account of the great beauty of their form and deep red color, the large size of their bags and the high condition in which they were kept, that I was at length induced to ask Mr. Winn, to what breed of cattle they belonged, and his reason for keeping them constantly in the stable, in preference to allowing them to run in the pasture, where they could enjoy the benefit of air and exercise, and at the same time crop their own food and thereby save the labor and trouble of feeding them? Mr. Winn in reply to these inquiries, stated, that the two cows which I so much admired, were of the common stock of the country, and he believed of *Spanish origin*—but that they were *both spayed cows* and that they had given milk, either two or three years. Considering this a phenomenon (if not in nature, at least in art,) I made further inquiries of Mr. Winn, who politely entered into a very interesting detail, communicating facts, which were as extraordinary, as they were novel to me, and supposing that they will prove equally as interesting to your numerous agricultural readers, as they were to me, I am induced, on the request of a friend, to offer them for publication in your very valuable journal, in the hope, that some of the farmers who supply our large towns with milk, will deem them of sufficient importance, to make experiments for the purpose of ascertaining whether the results which they may obtain, will corroborate the facts stated by Mr. Winn, and which, should they be fully confirmed, may lead to great and important benefits, not only to farmers, but to tavern-keepers and other inhabitants of cities, and villages who now keep cows, in order that they may be sure of a constant supply of *pure* and *unadulterated* milk.

Mr. Winn, by way of preface, observed, that he had in former years been in the habit of reading the English Magazines which contained accounts of the ploughing matches which were annually held in some of the southern counties of England, performed by cattle, and that he had noticed that the prizes were generally adjudged to the ploughmen, who worked with *spayed heifers*—and although there was no connexion between that subject and the facts which he should state, it was nevertheless the cause which first directed his mind into that train of thought and reasoning, which finally induced him to make the experiments which resulted in the discovery of the facts which he detailed, and which I will narrate as accurately as my memory will enable me to do it, after the lapse of more than twenty years.

Mr. Winn's frequent reflections, had (he said) led him to believe—"that if cows were spayed soon after calving and while in a full flow of milk, they would continue to give milk for many years, without intermission or any diminution of quantity, except what would be caused by a change from green to dry or less succulent food."

To test this hypothesis, Mr. Winn caused a very good cow, then in full milk, to be spayed; the operation was performed about one month after the cow had produced her third calf; it was not attended with any severe pain or much or long continued fever; the cow was apparently well in a few days and very soon yielded her usual quantity of milk and continued to give milk freely, for several years, without any intermission, or any diminution in quantity, except when the feed was scarce and dry—but a full flow of milk, always returned, upon the return of a full supply of green food. This cow ran in the Mississippi low grounds or swamp, near to Natchez, got cast in deep mire and was found dead. Upon her death, Mr. Winn caused a second cow to be spayed, the operation was entirely successful, the cow gave milk constantly for several years—but in jumping a fence, stuck a stake in her bag, that inflicted a severe wound, which obliged Mr. Winn to kill her. Upon this second loss, Mr. Winn had two other cows spayed, and to prevent the recurrence of injuries from similar causes with those which had occasioned him the loss of the two first spayed cows, he resolved to keep them always in the stable, or some safe enclosure and to supply them regularly with green food, which that climate, throughout the greater part, if not all the year, enabled him to procure.

The result in regard to the two last spayed cows, was, as in the case of the two first, entirely satisfactory, and fully established, as Mr. Winn believed, the fact, that the spaying of cows, while in full milk, will cause them to continue to give milk during the residue of their lives, or until prevented by old age.

When I saw the two last spayed cows, it was I believe, during the third year that they had constantly given milk, after they were spayed.

The character of Mr. Winn, (now deceased) was highly respectable, and the most entire confidence could be reposed in the fidelity of his statements, and as regarded the facts which he communicated in relation to the several cows which he had spayed, numerous persons with whom I became acquainted, fully confirmed his statements.

At the time to which I allude, I endeavored to persuade Mr. Winn to communicate the foregoing facts to the late Judge Peters, then president of the Agricultural Society of Pennsylvania. But he was restrained from complying with my request by an extreme unwillingness to appear before the public, and peradventure, his discovery might prove not to be new, as doubts in regard to the facts, might, where he was unknown, subject him to some degree of ridicule.

The many and great advantages that would result to the community, from the possession of a stock of cows, that would be constant milkers, are too obvious, to require an enumeration.

Should gentlemen be induced from this communication, to make experiments, they will find it better to spay cows which have had several calves, rather than heifers, as at that age their bags are usually large and well formed, and are capable of carrying a much greater quantity of milk (without pain and inconvenience,) than younger animals.

VIATOR.

From the Richmond Enquirer.

PROCEEDINGS OF THE DIRECTORS OF THE JAMES RIVER AND KANAWHA COMPANY.

The Board of Directors re-assembled in this city on the 17th inst: Present—Joseph C. Cabell, President, John H. Cocke, Sidney S. Baxter, Randolph Harrison, Samuel Marx, and Richard Sampson. The Board continued its session for two days; and after rescinding the previous order for a meeting on the 24th inst., adjourned to the 17th of July. A variety of business was transacted at the last meeting; but the attention of the Board is understood to have been chiefly engaged in organizing the Corps of Engineers. That organization was effected, so far as it was required to prepare the First Division of the Canal for immediate execution; and it was framed upon consultation with Judge Wright, of New York, who was in attendance by invitation of the President, under authority given at the previous meeting of the Board. The Corps of Engineers will consist, for the present, of an engineer in chief, three assistant engineers, three surveyors, six rodmen, and six chain-carriers. It will be divided into three divisions, each consisting of one assistant, one surveyor, two rodmen, and two chain-carriers. The line of canal from Lynchburg to Maiden's Adventure, will be divided into three sections: one extending from Lynchburg to Tye River, another from Tye River to Scottsville, and another from Scottsville to Maiden's Adventure. A division of the corps, will be assigned to each section of the line, and they will commence their action about the same time, and as soon as practicable, and locate downward. Each assistant engineer will have authority to employ two axemen, and each division will be attended by a covered boat, conducted by a boatman, who will act also as cook to the party: and will also be furnished with a cooking apparatus, and with tents, for the purpose of encamping at night upon the hills, and beyond the reach of the dews and the fogs of the river. The residue of the furniture of the boat, as well as their provisions and instruments, will be furnished by the members of the division, whose compensation is regulated with a view to that object. The boat attached to each division will slowly descend the stream, keeping abreast of the party as the location proceeds, so as always to be within convenient distance of the division.

Benjamin Wright of New York, is appointed engineer in chief; and although he reserves his final acceptance or non-acceptance till after his return to New York, there are the best grounds for the belief that he will accept the appointment. This distinguished engineer, whose services are so extensively sought for, was already under extensive engagements, leaving him about one-third of his time for the residue of the current year, and two-thirds in future years. The latter proposition, it is hoped, may be reduced to three-fourths, by a compromise with the companies to which he stands engaged. The periods of his absence in future years will be selected with reference to the convenience and interests of our work, and upon consultation with the president of the company. His salary for the residue of the present year, will be at the rate of $3000 per annum. For future years, it will be at the rate of $5,500 or $6,000 per annum, just as he may spend 8, or 9 months per annum in the service of the company. This rate of compensation may appear to be high to those at a distance from the great lines of improvement, but will be deemed very reasonable and moderate, to those acquainted with the high profits of the profession, and the vast importance of professional skill, in works involving the expenditure of millions. The most eminent engineers in the United States are in the receipt of from $10,000 to $15,000 per annum, for the various lines under their care, and in the habit of receiving $5,000 for laying out, and making an occasional visit to a single line. In the selection of his *three first and principal assistants*, and in the adjustment of the amount of their salaries, Judge Wright is understood to have expressed a particular wish to be consulted, in which he was gratified by the president and directors. This proceeded from the very great importance to himself and to the Company, that he should be aided by tried and skilful assistants, upon whom he could implicitly depend in the location of the canal.

Charles Ellet, Daniel Livermore, and Simon W. Wright, were elected assistant engineers, each with a salary of $2,000 per annum. It is understood that these engineers are of many years' experience in the line of location, and that these are the rates of compensation which some, if not all of them, are now receiving elsewhere, and the least for which their services could be procured.

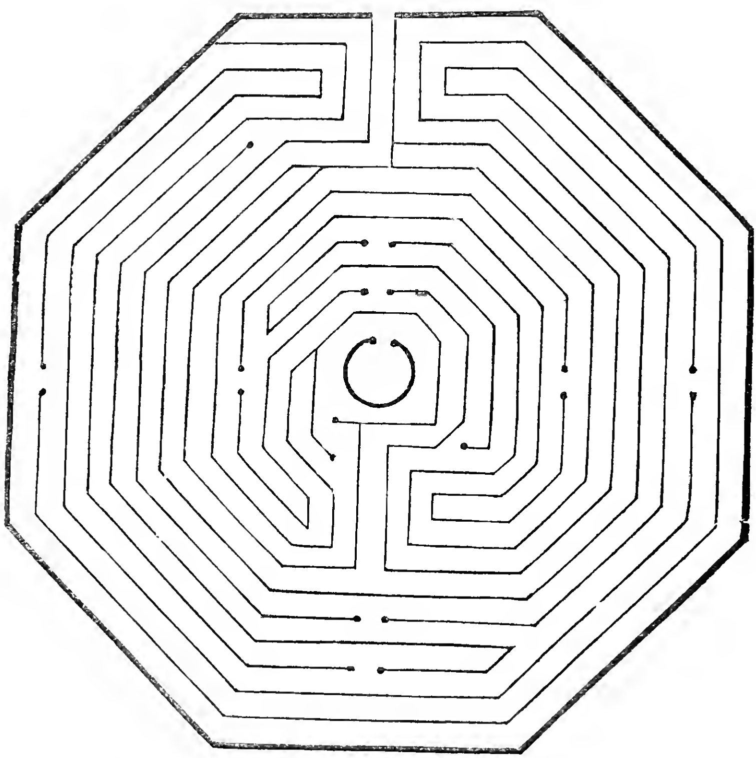
The surveyors, rodmen, and chain-carriers, will be appointed by the president, in conjunction with the assistant engineers. It is understood that those appointments will be speedily and advantageously filled, from a list of numerous applicants from within the limits of the state, who are well educated and seek to enter the profession of engineering with a view to future distinction, as well as the means of subsistence.

It is hoped that the whole corps will be organized and equipped for the field by the 15th July, and that the three divisions will be in motion by the 20th of the month.

For the Farmers' Register.

PLAN OF A LABYRINTH, FOR A PLEASURE GARDEN.

The plan below, will probably be found to accord with the object in view more completely than would be supposed possible from employing so few lines, and in so small a space as this might be constructed on. The difficulty here designed, (like that of the labyrinth within which tradition tells that Fair Rosamond was concealed,) is to find the way *in*—and not *out*, as was the difficulty in the Cretan labyrinth. Indeed, one part of the purpose and effect of this is to bring the seeker frequently outside of the entrance, when he supposes he is making fast progress towards the centre. If on this plan a labyrinth was constructed by walls or paling, with passages of sufficient width, it would not cover a quarter of an acre: and if constructed in a public pleasure garden, of a city, would serve to furnish as much amusement to visiters, and profit to the proprietor, as could be obtained at no greater cost.



COMPARATIVE VIEW OF THE AGRICULTURE OF VIRGINIA AND THE NORTHERN STATES.

To the Editor of the Farmers' Register.

* * * * * * *

When I began this letter I did not think of writing on any other matter than the one I have mentioned, but while I have my pen in hand I will add, that though I highly approve the general conduct of your publication, and I find a remarkable coincidence in our opinions on agriculture. I occasionally meet with some very fanciful, and, as I think, some very erroneous opinions among your correspondents. This I know cannot be avoided in such a work, and perhaps if it could, it ought not to be: as arguments on different sides of a question often aid in coming to a right conclusion. But I think that a greater number of your correspondents than I could wish, seem disposed to compare our agriculture with that of the northern states, much more unfavorably than is warranted by facts. In page 730, Vol. II, I find a very neat and well written article by a correspondent, on the agriculture of Rhode Island. A few years since I spent a part of the hot season in that delightful spot, and do not wonder that he is so much enamored with it. The scenery is beautiful; and the morning fogs, and cool and moist breezes from the ocean cover their meadows and pastures with verdure; but I did not think their agriculture superior, nor indeed, by any means equal, to that of the generality of fertile and well managed estates in Virginia. That their crops of onions and potatoes are much better than ours, is, I think unquestionable; and this I believe is mainly owing to the climate. Their onions, which are a field crop, are sown in the spring, throw out a great number of offsets that cover the ground, and do not come to maturity till the cool weather of autumn sets in: they will then bear transportation to the New York and southern markets. The onion with us is of no value but as a garden crop. It must be sown late in the season, and the button onions transplanted in the spring; they make very few offsets, and come to maturity in the heat of summer. They must then be gathered, and being subject to rot at that season, it is with much difficulty that a small supply can be preserved for family use. As to potatoes, which are a valuable crop in Rhode Island, and shipped from thence in large quantities to different markets, I think they are of no value with us except for the table, and then chiefly for use in summer, and a little later.—In the autumn and winter they are very inferior to those we get from the north. This difference I think, is owing to climate. If planted in the spring they come to maturity, like the onions, in the heat of summer—are preserved with difficulty, and are besides, except early in the season, of a very inferior quality, hardly fit for table use. At our Virginia springs, and in the recesses of the Allegany, I think the potato is decidedly better than in Rhode Island or Connecticut, and only inferior—if it be inferior—to those that are brought from Liverpool. This difference too, I think, attributable to climate—the summers being generally cooler in our Allegany country than in those parts of New England.

As some time has passed since I was in Rhode Island, I hope their agriculture has since improved—there was certainly much room for it, and I cannot otherwise account for the very favorable view your intelligent correspondent has taken of it. The pastures, (which were well stocked with sheep as well as horned cattle,) and their meadows were, I think, pretty free from annual weeds, as lands that have been long in grass generally are; but both appeared to me to be in a rather slovenly condition, with a good deal of "rubbish, briers, bushes, &c." in spots. Their ploughing I thought decidedly inferior to ours; nor did I wonder at it—their ground being much encumbered with stones, and their ploughs drawn sluggishly and heavily by oxen. With regard to their crops of corn, I agree with your correspondent in thinking them very good; but they did not appear to me to be in as clean order as ours generally are on our best, or even on our inferior lands. This perhaps was owing to the moisture of the climate favoring the growth of weeds. I observed the hills of earth round the corn which he mentions, a fashion which formerly prevailed in this country, and has long since been changed, I believe with good reason—and supposed it might probably be a good practice on lands unsheltered by woods, and exposed to tempestuous winds from the ocean. I can easily believe that the crops occasionally amounted to ten barrels the acre, and think it not more than ought to be made on lands originally strong and manured "*ad libitum*" as well by the marine weeds your correspondent mentions, as by the large stocks of cattle, sheep and hogs which are kept on the island, of which it appeared to me that at least five-sixths were in meadow and pasture. Without controverting the account your correspondent gives of the produce to the acre, I can say for myself, that in travelling through the northern states, and in our mountain country, I have seldom if ever been able to get any other than conjectural accounts. Ask a farmer in Pennsylvania or our mountain country, how much wheat he made for market the last year, and he will tell you to a bushel, for he has his miller's receipts for the whole: but his corn being got out at different times, as leisure from the other business of his farm admitted, and not being regularly measured, he can seldom give any certain account of it.

As to the rare-ripe corn planted in Rhode Island, it is no doubt suited to that climate, as our good old fashioned gourd seed is to ours. If we were to plant their sort, and they ours, I think both would fail in a crop.

I take it for granted the implement for raking stubbles, of which your correspondent gives a cut, is unknown in his part of the country, and probably in other parts of Virginia; and he has acted properly, and I hope rendered a service to those districts, in publishing an account of it. In my neighborhood, just such an one has been long and pretty generally used on the large wheat plantations, and I think a good deal of wheat may be saved by it if the season has not been so wet as to injure the wheat lying scattered on the ground.

I trust you will not understand me as being disposed to to censure your correspondent in any particular. He is evidently a very intelligent person, and I doubt not, writes with perfect candor. Indeed I should not have thought of mentioning to you any difference between his opinions and mine, if mine had not been different from those of many of your correspondents in regard to the superiority of the agriculture of the northern states over ours. I have more than once gone over the usual track of travellers in New England, New York, (except its rich western country,) Jersey, and Pennsylvania, and have long been of opinion (perhaps erroneously) that except from the farmers, generally Dutch, on the rich lands of Pennsylvania, we have little to learn at the north in the management of our usual crops. I have seen a great deal of as good ploughing in Virginia as I have ever seen at the north, and I think we can fairly compete with them in the whole management of our grain crops. Still I freely admit that with us there is great room for improvement.

It would give me great satisfaction to be able to hold the opinion of numbers of your correspondents, that the soil of our middle and lower country was originally, in general, a fertile one, and that it is steril only through bad management. That there were, and now are, in both these districts, considerable tracts of rich land, I freely admit, and I wish I could persuade myself that this is the general character of our soil: but I have long thought that the very indifferent crops that we raised on a great portion of our lands are so, as much or more, from the land being infertile, or from bad cultivation. As a great part of the country is still covered by its native woods, it seems to me unquestionable that these lands are generally in the same state with regard to fertility, that they were at the first settlement of our country, and any person at all capable of judging, would, from the growth of wood on them, at once pronounce them to be naturally infertile; and if, not regarding these indications, he should examine the soil and find it thin, light, and sandy, or a stiff pipe clay, or gravel, and on investigating the sub-soil in ravines and gulleys, he should find it sandy, gravelly, or resting on sandstone or granite, he would come to the same conclusion. There are, however, some circumstances in favor of this, comparatively, unproductive soil. It generally lies well, is free from stone, and is easily cultivated. I may very probably be mistaken, but I have long thought that our climate is a very favorable one to grain crops, especially Indian corn, which is so valuable, and so productive.

With these views I am far from despairing of the improvement of the soil of lower and middle Virginia. Our rich alluvial soils, though they do not form a large proportion of the whole, are of considerable extent. So far as I am acquainted with them, they are generally well ploughed, and the crops well managed. The greatest fault in the husbandry of these lands, as I think, is the perpetual recurrence of exhausting crops, and in most instances, (though there are numerous exceptions,) a want of due attention to the collection and application of manures. A great proportion too of our higher and less fertile lands I think are capable of great improvement. The inexhaustible beds of the richest shell marl which have been already found in almost every part of our lower country, and which I am persuaded are but a small proportion of those that actually exist, with the aid of animal and vegetable manures, will by degrees fertilize this district; and I hope you will see the day when this improvement, to which you have so largely contributed, is extended through the greater part of it.

Our middle country, notwithstanding some slight indications to the contrary recorded in your Register, I fear is generally destitute of marl. This range of country commonly rests on granite or other rock that I believe geologists denominate primitive, and I understand that marls do not belong to this formation. I believe that limestone has not been found in this district, except a small stratum that runs through the country about twenty-five miles from the Blue Ridge, and nearly in the same direction. However, the soil of the middle country being generally stiffer than that of the lower country, is better suited to clover, and much may be done toward the improvement of this region by crops of clover, aided by gypsum, with animal and vegetable manures. A practice (whether a new one or not, I cannot say,) is now gaining ground in a part of it, probably not elsewhere, of top-dressing wheat, as well after, as at the time of seeding, with the farm-pen and stable manure; and I am assured that clover seeded on it in the spring, even upon thin land, seldom fails to turn out a heavy crop. Still whatever plan of improving on our less fertile lands is adopted, I am fully persuaded that a rapid succession of exhausting crops will soon return them to their original state, or reduce them still lower, unless they are kept up by liberal supplies of manure.

Having already advanced the opinion that our agriculture, so far as it relates to the management of our usual crops, will bear a comparison with that of the northern states in general, I ought perhaps to advert to one point of comparison in which the agriculture of the New England states, a great part of the other northern states, and of our mountain country, has the advantage of ours in the middle and lower country. The climate of those regions being cooler and more favorable to the growth of herbage than ours, and a great proportion of their soil being very hilly, or encumbered with stones, it is less suited to the plough. It is a natural and almost necessary consequence, that pastures and meadows should occupy a much larger portion of their land than of ours—that they should have much larger stocks of cattle—and a much smaller proportion of their soil being under the plough, they are able to manure it much more heavily than we can possibly do. In New England, we seldom see a field of corn that is not highly manured: our very extensive fields get little, and much the larger part no manure at all. Their crops, of course, ought to be much heavier than ours. This difference then, between their system of agriculture and ours, seems to be mainly owing to natural causes, that are, in a great measure, beyond our control. Both our climate and soil being better suited to the plough than to pasture, our course of husbandry is, I am afraid, necessarily an exhausting one; and though we may countervail this tendency in some degree, I have never heard of any system of management, that in my opinion, seemed likely to do it effectually. The plan that is most generally approved, is to keep the arable lands that are at rest, free from the tooth and hoof of stock; and as all our cleared lands are arable, to have as small a number of sheep and cattle as possible—and that small number is generally deemed injurious to the soil. I am persuaded that our arable lands, during the short periods of rest that are allowed them, will be better able to bear a new succession of scourging crops if the natural grasses with which they clothe themselves, or the clover that is sown on them, are suffered to grow and decay without being fed off. But I believe none but our most fertile lands can be improved, or even kept in heart, by this course of husbandry, and that the less productive lands can only be improved under such management by manuring: and how is manure to be obtained without stocks of cattle? It may be urged that straw, corn-stalks, leaves, &c. will furnish as large a supply of manure, if spread on the ground, without having been used as litter or food for cattle. This is contrary to general opinion in England, and the other well cultivated countries in Europe; and I think it will be admitted, that vegetable substances are more speedily brought into a fit condition for manures, by being trampled and fed on by cattle, than if left to natural decay. It seems equally clear, that animal manures are much stronger than vegetable. Inclining as I do to these opinions, I am disposed to think, that in avoiding, as far as is practicable, the pasturage of cattle on arable lands that are under cultivation, during the short periods that they are at rest, it would be a good practice to lay off a part of the cleared land of a plantation for a standing pasture, selecting generally that portion that is least suited for grain crops, and to keep on it as large a stock of cattle as it will maintain during the season of pasturage, and as can be provided with forage from the plantation for the rest of the year. It is hardly necessary to add, that while the horses and mules are well littered, and well fed in stables, the cattle ought to be treated in the same way, in well sheltered pens, either permanent or moveable, as is thought most convenient, but so situated that the liquid manure cannot run off and be lost.

With regard to the proportion of a plantation to be laid off for a standing pasture, each case must depend on its own circumstances; but I would not venture to recommend as a general practice, any great or sudden change, that would very much reduce the annual vendible products of the plantation. Though the ultimate object of agriculture, like all other pursuits of industry, is profit, which comprehends the improvement, and of course the increase in value of our land, most of us rely on the annual products for our support.

If this were written for publication, and should be inserted in your Register, I have little doubt that I should subject myself to the imputation of preaching heretical doctrines, in recommending an increased stock of cattle, and the high and most respectable authority of Col. Taylor would be quoted against me. Perhaps in defending myself, I might rely on the ancient adage "*Amicus Plato, &c.*;" but I think there would be no occasion for it. In the main, I agree with him, that arable land, when at rest in the course of crops, should not be pastured closely, if at all, and only recommend, under circumstances, such a stock of cattle to be kept in standing pasture, as will be nearly, or quite sufficient to consume the herbage of the plantation, and improve the quality, as well as increase the quantity of manure.

In the application of manures, I think some of our good farmers, in other respects, have much to learn. I have seen the bulk of the manure, on well cultivated plantations, applied liberally to galls, to remove an "eyesore," and to the thinnest soil of a field, to bring it on an equality with the more fertile part; though that too wanted manure to raise it to the proper standard of fertility.

It is a very general opinion, in which I heartily concur, that wheat husbandry cannot be conducted to advantage, unless clover is grown as a preparation for wheat, and a heavy crop of wheat can hardly be expected; except on rich land, unless it is preceded by a good crop of clover. But a small proportion of our land is strong enough to bring good crops of clover without the aid of manure, and I think it would be much better management, when there is not manure enough for a whole field to be seeded with wheat followed by clover, to apply it in sufficient quantities to a part of the field, and that not the worst, than to give a very light dressing to the whole field, which would only give a light scattering crop of clover. In the former case, a part of the land is at once brought to the proper point of fertility, and the residue in its turn may be treated in the same way. Whether the bulk of the manure should be applied to the corn crop preceding wheat, spread before the wheat furrow, or applied as a top dressing to the wheat, the manure will produce its effect in either way; but from what I have seen and heard, I am satisfied that a top dressing, at or after the time of sowing wheat, will insure a good crop of clover on lands that otherwise would not bring enough to deserve the name of a crop.

In different accounts that I have seen of Scotch husbandry, it is stated that the arable lands in that country having been generally much exhausted, a system of husbandry called, I think, the "in and out-field," was introduced. The in-field lots next the farm buildings, were heavily manured, and thrown into a separate rotation of crops. The out-field lands were occasionally cultivated for such crops as they could get with little or no manure. By degrees, with the aid of heavy crops of clover and increased quantities of manure, the farmers were enabled to extend their in-field lands, and now a great part of the arable lands in the low lands of Scotland are cultivated on the in-field system. A practice like this, I am told, has been followed in some parts of the northern states, and with like success. I understand too, that some of our most successful tobacco planters have laid off lots which they cultivate in a rotation of clover, wheat and tobacco, to great advantage.

I observe that for some time past, a controversy has been going on in your Register, with regard to the proper rotation of crops. This is one of those subjects on which "much may be said on both sides," and very judicious observations have been made by the advocates of opposite opinions. It must be admitted, that this is a subject of importance to our husbandry, but whether the three, four, or five-shift system is followed, there may be very bad or very good management with either rotation. On those plantations where wheat is a principal crop, if good crops of clover can be obtained, and a plentiful supply of manure furnished, good crops can be made on either system; though according to circumstances, one system may be preferable to another. Our kitchen gardens are constantly cultivated in a succession of crops, all more or less exhausting; but with sufficient supplies of manure, their fertility is kept up —without them, the soil would soon be worn out.

I cannot conclude this long letter, already by far too heavy a tax on your patience, without again adverting to the letter of your correspondent on the husbandry of Rhode Island. He says, "*I should think that one Rhode Island laborer would perform as much as two and a half southern slaves.*" Now there is nothing peculiar in this remark, as similar opinions with regard to the northern white laborers and our slaves, have been advanced in your Register, and so far as my memory serves me, without much, if any thing, being said on the opposite side of the question. I have often heard such opinions advanced in conversation, by highly respectable and intelligent persons. I think I have had sufficient opportunities of comparing these two very different classes of laborers, and right or wrong, though certainly meaning to be right, have long been of opinion, that man to man, our slaves perform as much or more labor, and perform it as well or better, than the laborers at the north, or at least beyond Pennsylvania. Without going into long details, let us look at general results. In the Blue Book (as it is called) for 1834, App. p. 34, is an account of the domestic exports of the United States, for the year 1832.

The agricultural exports are—

Product of animals,	$3,179,522	
Vegetable food,	352,494	
		$11,532,016

		$49,416,183

Thus we see that cotton, a product obtained wholly by the labor of slaves, was in 1832 largely over two-thirds of the whole agricultural exports of the United States; since that time the ratio has greatly increased. Add to this the tobacco, of which I am persuaded more than nine-tenths are produced by slave labor, and the vegetable food of which I think you will agree more than one-half consists of the wheat, Indian corn, and rice, raised by the labor of slaves. After this simple state of undoubted facts, can any judicious well informed person doubt that slave labor in agriculture is more efficient and productive in the southern states, than free labor directed to the same object at the north? Will it be said that the domestic consumption of the produce of our lands is greater than the export? Without denying this as a fact, I would ask what proportion of the bread stuffs, the rice, the sugar, and molasses consumed by the people of the New England and other northern states, to say nothing of tobacco, is the produce of slave labor at the south?

I may be mistaken, but it has long been my settled opinion, founded on full, and I hope impartial consideration, that there are few countries where agricultural labor, by the same number of hands, obtains as large and valuable products as the slave labor of the southern states.

This is not written, I assure you, in the spirit of controversy, but I hope from a better motive. It is right and proper that we should be stimulated to improvement in our agriculture, and there is too much room for it: but why should we so often be presented with so gloomy a picture of our husbandry, as compared with that of the northern states? It would not perhaps be too strong to say, as Mr. Jefferson said on a different occasion, "in this I neither recognise the portrait of ourselves, nor the pencil of a friend."

You will not understand me, I hope, as meaning to cast any censure on the northern husbandry. The farmers of New England, and the other northern states, whose management I have had an opportunity of observing, appear to me to be a class of men that would do honor to any country —steady, active and intelligent, their farm buildings, their implements, their working cattle and other stock, are generally in good order, and well attended to, and among them there are instances of farms well cultivated throughout, especially in the fertile valley of Connecticut River. But their husbandry in general did not seem to me to deserve this character. This I was satisfied, on inquiry and consideration, was owing to a course beyond their control. The scarcity, or in other words, the dearness of labor—a large proportion of their hands being employed in navigation and manufactures at high wages, farm laborers would of course require more for their services; and such neat husbandry as is practised in fertile and well cultivated lands in Europe, would cost more than its worth. They seemed to me, in passing through their country, to be careful, rather than laborious. The leisure of the shepherd and herdsman, and the toils of the plough and sickle, have always been a subject of remark, and a fruitful theme of poetry, ancient and modern.

For the Farmers' Register.

MONTHLY COMMERCIAL REPORT.

Agricultural produce generally continues to command high prices. A state of peace throughout the world has doubtless tended to increase the consumption of nearly all commodities, whether of luxury or necessity. The facility of intercourse between all countries opens new markets, and furnishes a greater variety of articles of commerce adapted to our wants, improvements, or inventions. For example, the increased use of iron for rail roads and other purposes is beyond computation— and to what various uses is ingenuity applying the formerly insignificant article, caoutchouc or India rubber!

The amount of domestic exports from the United States will be greater this year than in any former one. The value of cotton alone, at the high prices of this crop, will exhibit an amount nearly equal to the usual aggregate of all domestic articles exported. Although the quantity of cotton produced last year was full 50,000 bales more than in any former one, the demand has increased in a greater ratio, and the price it now commands (18 to 20 cents) is higher than at any period since the memorable and disastrous speculations of 1825. There appears to be no cause to apprehend a similar result during the current year; but as the extension of culture in the United States is annually very great, and the inducement of high prices must also increase the growth in other countries, the supply must ere long overtake the demand, and the price recede to a rate which will reduce the profit of cultivation to a level with that of other commodities.

Meanwhile, the emigration to the south-western states is immense, and the value of their lands, and of slaves to cultivate them, greatly enhanced. Virginia, and the Carolinas, supply so large a part of this population, as to diminish their resources, retard their prosperity, and reduce the value of landed property in those states, except such as is very productive, or favorably situated.

The cultivators of tobacco are, however, very amply remunerated for their labor, and with a considerable increase of the quantity produced, the price continues very high—25 to 50 per cent. more than for several preceding years—the extensive sales now made being at $6 to $17 per 100 pounds, and in some instances $20 to $30.

The price of wheat will no doubt be higher this season than usual; but the advance will scarcely be sufficient to compensate for diminished production in Virginia, where the crop has suffered greater injury than perhaps in any other part of the country.

In addition to the regular commercial transactions, which have been unusually large, a vast extent of speculation has also prevailed, chiefly in the northern and western cities and states. Landed property has there changed hands at prices far beyond what it had previously commanded. In the cities and their vicinities, the enhancement has been double, treble, even ten-fold, and fifty-fold in some instances. Population must increase with great rapidity, and the prosperity of the country be unchecked—or the value of money decrease by excessive issues of bank paper, to sustain such speculations—if former experience is any rule. The unfortunate result which attended a similar rage for property in Virginia some years ago, has probably operated as a warning against repeating the experiment here.

The stocks in the Petersburg, and in the Richmond and Potomac Rail Roads, have got into favor, both at home and abroad. The former paid a dividend of 4 per cent. for the last six months; and the stock has been sold in Philadelphia at $110 per share. In the latter company, on which $25 per share has been paid, an advance of $7 is obtained: the work is proceeding rapidly.

The transportation on the Petersburg Rail Road is steadily increasing, and the Greensville Road to connect with it, is now in the hands of the engineers. Works of a similar description, and to an immense extent, are in progress in every part of the Union, with the exception of North Carolina, where a favorable opinion of them begins to be entertained.

X.

June 25th, 1835.

SEASON AND STATE OF CROPS.

Accounts from nearly all quarters of the state continue to speak of the prospect of the wheat crop in Virginia as very bad. The only exception is from the Ohio River, on the borders of which the wheat is said to be good. The highest estimate that we have heard of elsewhere, of the probable amount of any farmer's crop, is two-thirds of an average. These estimates were for lands of very good quality—which, if our limited observations may be confided in, will withstand the inflictions of this year far better than poor and middling lands. We have on middling soil, (such even as most persons would consider as deserving a higher rank,) whole acres together on which the wheat is not worth reaping—indeed has almost disappeared: while on about 35 or 40 acres of very good soil, and after a clover fallow, the crop is excellent, and promises a fair return for the quality of the land. The price however, as of every other crop, will be much higher than usual, and in some measure compensate for the deficiency in quantity. In the few extracts from the letters of correspondents annexed, together with other matters, more full statements on this subject are made, and from some parts of the country not previously heard from.

STATE OF CROPS IN ALBEMARLE, AND THE VALLEY.

To the Editor of the Farmers' Register.

Albemarle, June 9th, 1835.

The prospect of the wheat crop in this county is really gloomy. The same causes which have produced the disastrous effects in other sections of the country have operated with us, to wit: the extreme severity of the winter frosts, and the unprecedented ravages of the Hessian fly. From my own observation, and the best information I have been able to collect, I feel confident that not more than one-fourth of an average crop will be made in the county. It is true, there are some instances where a large proportion will be realized—some a half, and perhaps a few favored ones rather more; while many others will scarcely produce more than the seed sown; so that upon the whole, I think my estimate of one-fourth of a crop, will be found not far from a correct one, judging from present appearances; but an unfavorable state of weather from this time until harvest, may even curtail the crop below that estimate. The harvest will be a very late one; little, if any, will be cut in this month—this being the fact, and the thinness of the crop on the ground, will render it more liable to receive injury from rust. I have had an opportunity of viewing the crops in the two adjacent counties beyond the ridge, Augusta and Rockingham, and I think the prospect in both were equally, if not more unpromising than in Albemarle. I understood from good authorities, that the failure was nearly general in all the valley from the Alleghany to the Potomac. The same unpropitious account will apply to all the counties I have heard from immediately below the ridge, as well as the counties south of James River from Lynchburg to Danville. It is said that the crops of wheat in the neighborhood of Charlottesville, are likely to yield a better crop than in any other section of the upper country. The corn crop is backward for the season, but now growing finely—oats promising—clover only tolerable. I hope the remaining part of the season will be more propitious for the farmer, and that we shall yet realize, if not an abundant, at least a saving crop of corn—so important under our present circumstances.

WM. WOODS.

USE OF CLOVER AND GYPSUM COMMENCING IN NORTH CAROLINA—STATE OF CROPS.

To the Editor of the Farmers' Register.

The perusal of your Register has induced me to commence some experiments on clover and gypsum, which, from present indications, promise to realize the most valuable results.

I have sowed about six bushels and a half of clover seed, (a large quantity for this section of country,) on about eighty acres of land, the greater part of which exhibits a luxuriant growth—that particularly which was sowed early, on land in wheat. That which was sowed with clover late in March, and harrowed, is not so good.

I have made an experiment with plaster and ashes mixed, with ashes alone, and plaster alone; the latter is evidently the best; the mixture next, and the ashes alone about equal to half of the quantity of the mixture. The experiments were made on an equal number of corn hills, with a given quantity of each of the manures, and on different soils.

I propose carrying out the experiments to the gathering of the fodder, and grain, the final results of which, with a more detailed statement of facts, I will furnish you.

The prospects for crops are, at this time, gloomy. Wheat (though better than some accounts state it to be in other parts of the country,) is far from being good. Mine is considerably blasted, and otherwise injured in the heads; perhaps by the chinch bug. Corn and cotton are generally unpromising, particularly the latter, which came up badly and stands worse. From present appearances, we calculate on a very short crop. Oats generally good, though suffering for rain.

Yesterday I cut my skinless oats, which were sowed a few days before I sowed the ruffle and common oats—none of which will be ripe enough to cut in a fortnight. To-day I have sowed a few of the skinless oats, cut yesterday, for the purpose of testing whether two crops of it can be made in this latitude in a year.

Only one of my pine nuts came up, and I fear that one will die. * * * *

W. B. LOCKHART.

Northampton Co. N. C., June 23, 1835.

EXTRACTS FROM PRIVATE CORRESPONDENCE.

Bertie County, June 1835.

Our crops at this place present a gloomy aspect at present. We have not had a "season" for four weeks. Our oat crop will be entirely cut off. Our corn is smaller for the present than I have perhaps ever seen it. Our cotton has come up badly. Some persons have had to plough up, and plant again.

Nansemond, June 18, 1835.

I thank you most sincerely for the present you sent me the other day, of your second edition of Calcareous Manures. So far as I have examined it, I find that the doctrines therein advanced are supported by my observation and experiments made with marl and lime, and I am clearly and thoroughly of the opinion, that we have within our reach an inexhaustible treasure—that our lands may be so improved as to yield an abundant profit, for any *reasonable* man. Let an *unreasonable* one go to the south, and speculate in the visionary schemes of the day, and either make his fortune, or get broke. * * * *

You can have no idea of the prejudices of many of my countymen against the improvement of the soil by means of calcareous earth, and though I have now a crop of wheat growing (upon land that would formerly bring nothing of value like wheat,) that would do any man good to look at, yet the people (save a few) will not believe that marl or lime had any agency in it—they say it was stable manure. What I shall make to the acre I cannot tell; but I verily believe 20 or 25 bushels to the average, and some 40 to the acre. It certainly is the best wheat I ever saw, either in eastern or middle Virginia, and gentlemen who pass the road from the mountains, say it is the best they have seen this year.

Brunswick, June 20th, 1835.

I am much indebted to you for the second edition of your Essay on Calcareous Manures; and whilst I am almost compelled to admit, that the position maintained in your 4th proposition on the different capacities of soils for receiving improvement appears to be tenable, that your reasoning seems to be sound and your conclusions just, I am not a little troubled with the conviction that the section of country in which I reside, cannot enjoy much of the benefit which will be derived from the information contained in your very useful Essay. And since I am so much troubled with the above conviction I should like to know of you with what effect clay ashes might be employed as a substitute for calcareous earth.

MISTAKES.

It is earnestly requested that all subscribers, after making payments, will examine the next printed list of receipts, and will immediately make known any omission or mistake that may be found. If this was done, with our course of procedure, there could not possibly be a mistake of two months duration. As it is, we are sometimes first apprised of them, when nearly two years have passed after the subscribers interested had the means of correction afforded them. Such occurrences are always unpleasant—and however promptly the few mistakes on our books have been rectified, when the proper information was offered, we have not always escaped giving offence, when entirely free, personally, from even the fault of neglect or carelessness. With every care to avoid such occurrences, we have not escaped making mistakes—nor can an entire exemption from them be expected under any circumstances. But our individual share of such errors is very small—and the means of speedy correction has always been offered in the list of published receipts.

But our subscribers make many more mistakes than all justly chargeable to us, or to former agents: and among them, there have been more overpayments offered, than all the overcharges caused by mistakes on our books. When second payments have been thus offered, the sums have been sometimes returned, and at others, entered to the subscribers' credit for a year later than they had stated. At other times, money has reached us for orders that could not be executed, and which were so carelessly expressed, that it was difficult to know where to return the sums. We now hold $10 thus sent three months ago, (from persons in Buckingham and Cumberland,) in a letter, without the writer's address, and concerning which we have written twice, and as yet in vain, and to different persons, to try to find out how to return the remittance.

TO CORRESPONDENTS AND READERS.

The advanced publication of one No. has served to bring forward all the mass of communications on hand, and we are now desirous of receiving, and ready to pay due and prompt attention to all others that may be soon sent in. So far as circumstances permit, we aim to publish communications as soon as possible after they are received and found suitable. None are held back to equalize the monthly publication of original matter: and therefore it may well happen, however abundant may be the supplies in general, that some Nos. may exhibit a deficiency. The first occurrence of that kind will be embraced to republish some old and long articles which well deserve to be made better known in this country, and which have been long ago selected with that view, but have been postponed for articles of present and more transient interest. Among these, are Strickland's Observations on the Agriculture, &c. of the United States, which it is believed has never been republished in this country, and has been seen only by a few of our farmers, in the bulky and very costly transactions of the British Board of Agriculture.

NOTICES TO SUBSCRIBERS.

Our subscribers at a distance, who are supplied through cross mail routes, have scarcely had the means of knowing, and therefore have not given due credit for the rare degree of punctuality with which this journal has been issued. During the whole time in which we have used the present publication office, the delivery of one monthly number only has been more than two days from the first day of any month—and then the delay of a few more days was made necessary by the editor's unavoidable absence, after the printing was completed. But delays, owing to various circumstances, sometimes occur after the packages are committed to the mail, and some of the post offices within 150 miles distance, may not receive their packages within two weeks after they have been mailed. Some causes of delay may be removed by changing one route from another—as sometimes the longest of two is the most speedy, or at least the most sure. Any information which can be furnished by postmasters or subscribers, pointing out proper changes of this kind, will be thankfully received. On the covers of this No. the day of mailing and departure will be stated, with the view of aiding such inquiries.

☞Subscribers are requested to read *at least once* the terms of publication. This request may appear superfluous and idle—but we often receive letters making inquiries, or professing ignorance of some of the plainest matters stated in the terms, and from old subscribers who have had them printed in more than a dozen of the copies which they have received.

NOTICE TO CONTRIBUTORS.

To each of the known contributors to the original matter of the Farmers' Register now on the subscription list, (not counting extracts of private correspondence,) a copy of the Supplement, containing the 2nd edition of the Essay on Calcareous Manures, has been presented, and sent by mail. Some persons have been necessarily passed over, for want of knowing their proper names or address—and probably others by mistake. It is requested that all such omissions may be made known, and they will be promptly supplied.

When stating in general terms, some months ago, the number of individuals who had written for the Farmers' Register, it was done without much regard to exactness, and only taking care not to state too large a number. Upon making a careful examination at the close of Vol. II, it was found that the prior statement was much below the truth, and that the actual number of contributors then was 215. The names of much the greater proportion of these still are subscribers to the Farmers' Register, and it is hoped that all will continue to add to their former favors—and in every successive publication there are presented the contributions of new and welcome aids. To all these friends we are indebted for the very existence of this work—and heavy as our obligation is admitted to be, still more of benefit has been conferred, by these contributions, on the agricultural community in general.

TERMS OF PUBLICATION FOR FARMERS' REGISTER.

1. The Farmers' Register is published in monthly numbers, of 64 large octavo pages each, and neatly covered, at $5 a year—payable in advance.

2. Or five *new* subscribers by sending their names and $20 at one time to the editor, will receive their copies for one year, for that sum, or at $4 for each. Purchasers of any 5 volumes (except Vol. I.) at one time in like manner, shall have them for $20.

3. The risk of loss of payments for subscriptions, which have been properly committed to the mail, or to the hands of a postmaster, is assumed by the editor.

4. For all copies not received by mail, duplicates will be furnished to those subscribers who have complied with their own obligations.

5. If a subscription is not directed to be discontinued before the first number of the next volume has been published, it will be taken as a continuance for another year. Subscriptions must commence with the beginning of some one volume, and will not be taken for less than a year's publication.

6. The mutual obligations of the publisher and subscriber, for the year, are fully incurred as soon as the first number of the volume is issued: and after that time, no discontinuance of a subscription will be permitted. Nor will a subscription be discontinued for any earlier notice, while any thing thereon remains due, unless at the option of the editor.

THE FARMERS' REGISTER.

Vol. III. AUGUST, 1835. No. 4.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

From the Genesee Farmer.

THE CULTIVATION OF WHEAT.

The following paper on the cultivation of wheat, was read before the Agricultural Society of this State at its meeting in February last, by H. Hickock, Esq. of Rensselaer county.

There are two causes which, when our winters are open, operate injuriously on wheat crops.—One is, the high and dry winds, which prevail in March; these blow off the soil in many situations, and by leaving the roots of wheat exposed, occasion their destruction. Another cause, is the heaving of the soil, occasioned by the alterations of cold and warm weather. The water in the soil, in the act of freezing, expands and raises up the earth, and also the roots of the wheat plants which the earth embraces when a thaw succeeds, the earth being heaviest, falls down first and leaves the roots of the wheat a little elevated, and by repeated changes of the weather, the roots are so far thrown out as to perish.

Farmers, when convenient, usually sow their winter grain early in September, upon a supposition which guides their common practice, that grain thus early sown withstands best the action of unfavorable seasons. This supposition, is founded upon the very plausible theory, that as the oldest roots will be longer and more numerous and take a firmer hold of the soil than those which are younger, they will be less exposed to be thrown above it, and at the same time, from their strength, be more tenacious of life. But experience informs us, that wheat, sown as late as the first or even the second week in October very often survives with less injury than that which is sown in the early part of September. Indeed farmers very generally admit, as the result of their experience, that rye, whose laws of vegetation must be nearly the same as those of wheat, sown so late in the season as barley to come up, is most likely to withstand an unfavorable winter. Still the very plausible theory, which has been mentioned, very generally induces them to sow rye early as well as wheat, in direct opposition to conclusions, which have been drawn from actual observation.

An experiment was made last autumn for the purpose of collecting some further information on this subject. On the first day of September last, I excavated a spot of ground six feet square. On the one side, the excavation was about six inches deep, on the opposite side, its depth did not exceed one inch. Seed wheat was placed over the bottom, so that the kernels were about four inches distant from each other, the excavation was then filled up. The soil was a suitable mixture of gravel, sand and clay, for wheat; and of ordinary fertility. This was the latter part of the extreme drought which prevailed last summer, and the soil was dry, warm and finely pulverized before it was thrown on the wheat. The circumstances, except the extreme dryness of the soil, were highly favorable to the vegetation of seed at the greatest depth in the earth. On the fourth of the month there was a heavy shower which not only wet the soil, but beat it down close and hard. On the ninth of the month, the plants began to show themselves; but none come up from a greater depth than about three and one-half inches. Two or three days after the second leaf had displayed itself, some of the roots were taken up and examined. It now appeared that nearly an inch below the surface of the ground, a new joint was found which was the basis of the second leaf, and also of a new system of roots. There were now two tiers of roots; the seed or knot adjoining it, had generated the lower tier, and the new joint the upper one. These two tiers or systems of roots were connected together by a root resembling a cord or thread, and in one instance, I cut off this connecting thread and transplanted the upper part. This grew with little apparent check from its curtailment; but the under part died, although the soil above it was opened so as to afford it the advantages of air and solar heat. On the 20th day of September, I examined another plant, which had its regular formations as expected, and, what was not expected, a blade was discovered about an inch long, which had started from the lower system of roots and would doubtless have found its way to the surface, had it not been disturbed. It is to be remarked, that this plant sprung from seed placed under cover of nearly four inches of soil, which was about an inch deeper than any of the other plants examined, and that some of the tops of the wheat plants had been eaten off and trodden down by accidental intrusion; a fact unregarded at the time. On the 26th day of September I examined another root, expecting to see the blade from below more perfectly developed, none however was discovered; but a third tier of roots was found at the surface of the ground, which proceeded from the second as that had from the first system of roots. On the 16th day of October I placed some seed wheat about two inches in the ground; their delay in coming up induced me to suppose that they had perished from cold and wetness; but at the expiration of three weeks they made their appearance, and although the ground remained open several weeks longer, no second leaf appeared, of course no joint or second system of roots had been formed. The very different formations in the roots of wheat, which this experiment has disclosed, proceeded from causes appropriate and capable of being ascertained, but to distinguish them with certainty, other trials must be made and conducted with greater accuracy than the one of which an account has been given.

From these experiments, though inaccurate, some conclusions may perhaps be drawn of practical use. All plants which live over winter, possess an apparatus, by which they supply themselves, in autumn, with food for their sustenance in spring. This food consists mostly of saccharine matter, which is enclosed in a proper receptacle. When this receptacle is formed near the surface of the earth, the fermentation of its contents is excited by frequent changes of weather, the saccharine matter is decomposed, and the plant perishes from the want of food, and perhaps also from a rupture of its vessels.

All wheat, shallow-sowed, must have its reservoirs of food but slightly covered with soil, and of course they are fully exposed. When wheat is sown early at any depth, a second, and sometimes a third system of roots is formed within an inch of the surface. In these, many stems originate, each of which has its receptacle of nourishment at its base, and it is quite certain that in most instances, the food, which was contained in the seed and the adjoining knot is entirely exhausted by the supplies of nourishment it affords the upper portions of the plant. The life of early sowed wheat must then, like that which is shallow sowed, depend upon the preservation of the reservoirs of saccharine matter which are placed at or near the surface of the ground, and of course exposed to the unfavorable action of variable weather during winter.

Wheat which is late sowed, generates no second blade or new system of roots, and of course, the nourishment for spring's use is retained in the receptacle which adjoins the seed. If then we sow sufficiently late in autumn, and place the seed deep in the soil, we shall provide every security against the hazards of bad weather, which the nature of the case admits of.

In the ordinary course of husbandry, some of the wheat is necessarily deposited at considerable depth in the soil, and when this takes place sufficiently late in the season, the receptacle of food will be protected by its covering of earth, and a partial crop will often be realized, although there may be, when the spring opens, no signs of life on the surface of the field. In such cases as the destruction of the blade, which issues from the seed-roots in autumn can be of little importance, one would suppose that the surviving plants will grow the more vigorously, from their being less in number, and by tillering produce many stems with large well filled ears; such, however is not the fact; usually the stems are single and the heads are not large. To account for this, it must be recollected, that after the ground has thawed in the spring, the earth settles and often becomes so extremely hard that doubtless many plants die, in their struggle to overcome the opposing resistance, and the surprise is, that any one should possess vigor enough to protrude even a single stem through the hard earth that covers it.

From this view of the subject, the practice may be recommended, of effectually harrowing the field in the spring after the ground has settled, in order to supply the plant with fresh air, and give a free passage to its upward growth. After the harrow has been used, the roller ought to be employed to reset such roots as have been displaced and diminish the evaporation of moisture.

In England, a wheat plant has been taken up, separated into eighteen parts and replanted, and by successive divisions and replantations, a crop of three and one-third pecks of wheat was obtained in less than eighteen months from the time the seed was sown. If the roots of wheat can be so minutely divided and successfully replanted, there is little danger that the freest use of the harrow can be injurious, provided the roller be also used. The fact appears to be, that nothing is necessary to theveral growth of the plant, but the preservation of the apparatus which contains the saccharine matter, which is its proper vernal food; so that if the roots and top be cut off, and the bulb be planted in a genial soil, the plant will grow.

Notwithstanding the arguments which have been urged in favor of sowing wheat late, it must be conceded that when early sown and our fields are cultivated in the usual manner, it produces the largest crop, if it survive the cold season. Whether such improvements may not be made as to combine the benefits of a sure and large crop, is a question still open to investigation; the probability is, that both advantages may be secured, by a more correct knowledge of the proper time to sow, and of the best methods of culture.

In the first volume of the transactions of the society for the promotion of agriculture, arts and manufactures, instituted in the state of New York, it is stated that in Huntington, Suffolk county, fifty-two bushels of wheat had been raised by manure on an acre of land, and Mr. Downs is said to have raised, on a poor, gravelly, dry soil, by the use of fish as a manure, at the rate of 128 bushels of rye per acre. In this case, the rye would doubtless have lodged and been of little value, were it not that it was twice eaten off by his neighbors' sheep which broke into the lot; once when the rye was 9 inches high, and again when it was about 6 inches high.

The production of so large a crop of wheat and of rye must have proceeded from causes which are steady and uniform in their operations, and if all the circumstances which had occurred to produce them had been distinguished and noted down, similar crops might have been again raised. Some things which occurred during the cultivation of this rye crop may be ascribed to accident or chance, so far as Mr. Down's sagacity was concerned, but the causes which proximately occasioned the crop, did not work by accident or by chance, but agreeably to the laws or rules from which they never deviate. This uniformity of operation lays the foundation for making future discoveries, and brings within the grasp of our faculties the knowledge of increasing our crops by methods the least laborious and expensive.

The period may arrive when the farmer shall pursue his methods of culture with an anticipation of the consequences which will result, analagous to that of the mechanician in the construction of a machine, and when, by direct means, he shall produce greater crops than ever were obtained by mere empirical trials.

Time was when the greatest philosophers taught the doctrine, that all things pertaining to the surface of the earth were too irregular and too much under the government of chance, to admit of scientific inquiry; this error has, within the two last centuries, been dispelled. But a similar error, in regard to rural affairs, is embraced by almost all our practical farmers, and the task of correcting and exposing it is devolved, it would seem, upon the unaided efforts of a few individuals. Here then is the difficulty.

From the Rochester (N. Y.) Daily Democrat.

UNPARALLELED SPEED UPON THE CANAL.

On Saturday, some forty or fifty of our citizens took a ride upon one of the new line packet boats, designed to run between this city and Buffalo. The boat is made considerably narrower than the ordinary packets; is exceedingly light, and finished in the most elegant manner. It is a sample of the workmanship of our enterprising and faithful fellow citizen, Seth C. Jones, who has for some time, we understand, been of opinion, that a boat might be so constructed as to be drawn by horse-power, at the rate of ten or twelve miles to the hour. The test on Saturday was a delightful realization of the fact. Although the horses were unaccustomed to the business, and for four or five miles of the distance, were exceedingly fractious and hard to manage; the ride was completed in two hours and thirty-four minutes, a distance of twenty-four miles, including changes of horses and a short stop at Spencer's Basin. It is found by experiments, that when the boat is propelled at the rate of seven and a half or eight miles to the hour, it rides upon the swell, creates less commotion in the canal, than the common packets at four miles to the hour, and requires, we believe, about the same power to draw it. An enterprising company has been formed to run a daily boat of this size to Buffalo, leaving Rochester after breakfast and going through by daylight, a distance of ninety-five miles! This will be "going ahead" on the "rail road principle," and those who are going from this to Buffalo, or from Buffalo here, we think it will not be difficult to say *how* they will go.

Extracts from an Address to the Essex County Agricultural Society.

ON IRRIGATION.

By Ebenezer Moseley, President of the Society, *September* 25, 1834.

The committee of the Essex Agricultural Society, on Irrigation, consisting of Daniel P. King, Hobart Clark and Moses Newell, report:—

That their attention was invited by Mr. Ebenezer Jenkins of Andover, to four acres of mowing land on which he has been making an experiment in irrigation. The field is a sandy gravel, the kind of soil most capable of improvement by watering, and so situated as to be flowed at pleasure. Mr. Jenkins bought of a neighbor the use of the water and the privilege of digging through his pasture for ten years, for twenty dollars; he then built a dam across a constant stream and made a channel about fifty rods in length; by means of this and other smaller ditches, he conducts the water on his field in such quantities and at such times as he thinks proper. Mr. Jenkins states that it is his practice to bring the water on the last of April, and to stop flowing about the 25th of June. In the spring of two years out of the four that his land has been in a course of experiments, he has applied a very light top dressing. The experiment has been successful and creditable to the enterprise of Mr. J: the average crop of grass for a number of seasons, according to the statement of several disinterested and judicious farmers, had not exceeded 10 cwt. to the acre: for three years past it was nearly equal to 30 cwt. and the present season, was judged to be two tons to the acre; the quality of the hay is good, and it would command a fair price in the market.

Irrigation, though long and extensively practised in other countries, has been but seldom attempted here. That it might be profitably employed by many farmers is probable: that it has been so employed by Mr. J. is certain. We will offer him a few suggestions; if the trial should not prove them to be improvements, he will have the additional merit of having extended his experiment, and having proved many things, he can hold fast to that which is good.

We think he should commence flowing earlier in the spring, and draw off the water sooner than the 25th of June; his grass would be ripe earlier, and by bringing on the water directly after the hay is housed, he would probably secure a heavy second crop. If his top dressing were applied in the fall instead of the spring, it would protect the grass in the winter, and might be productive of greater advantage. Mr. J. in his statement remarks that "observation and judgement are required to know how and when to apply the water," we agree with him, and offer our hints with some distrust of our ability to advise him. The writers on the subject whom we have consulted, recommend a course different from his in some respects. They say that the night, and cool or cloudy weather are to be preferred for bringing on the water. They also give a general rule, that no water should be applied, (unless in time of drought,) when the grass is tall and nearly full grown, as it might cause it to lodge, might make it gritty, or give it an unpleasant taste.

In our opinion Mr. Jenkin's experiments and statement are satisfactory, and entitle him to a premium of $20 00

Respectfully submitted by,

DANIEL P. KING.

New Rowley, Sept. 25th, 1834.

Ebenezer Jenkin's statement, to the Committee of the Essex Agricultural Society, on Irrigation.

Gentlemen—I present you with the following as a statement of my method of irrigating my mowing land. In the spring of 1831, I purchased of a neighbor for twenty dollars, the privilege of conducting the water from a constant brook, through his pasture, for the term of ten years: I then made a canal or ditch about fifty rods in length, after constructing a wooden dam across the brook; and on the 31st of April conducted the water on to one acre of sandy field land. This land has a gentle slope towards the south, had been four years in grass and the average crop was about one half ton. I stopped the flowing of the water, June 25th. The hay when made was estimated by judicious neighbors to be two tons.

In 1832, I continued and extended the experiment. On the acre above named, I obtained about two-thirds as much hay as last year. On the two acres, covered with water, for the first season, I obtained by estimation three tons of clover hay. Method of flowing the same as in 1831.

In 1833, I applied a light top dressing of compost manure, which I obtained by ploughing a yard where I had watered my cattle one winter. It amounted to about four cords, was mixed fine, thrown into a heap where it laid through one winter, and was spread in the spring. I obtained this year by estimation from 23 to 27 cwt. per acre.

In 1834, in the spring, I spread on about four acres eight cords of compost manure which I bought for $2 50 per cord. The water was used as in former years. The crop of hay has been estimated by several farmers at from 30 to 40 cwt. per acre.

It is not in my power to detail accurately the manner of using the water, as no two seasons are alike. Observation and judgement are required to know how and when to apply the water. I let the water on whenever we have a severe shower, for the benefit of the wash, which as you will perceive on viewing the land and brook, is great. I consider the water of greater benefit when the sun shines, than in cloudy weather at the same temperature, as the water draws the sun, and the warmer the water is, the faster the grass will grow. In the season of 1832 the frequent rains deceived me: on such sandy land we have seldom rain enough to supply the wants of the grass: in that year I think I did not bring on water enough. The actual expense of my experiment and the top dressing I have named, I estimate at $58.

Respectfully submitted by,

EBENEZER JENKIN'S.

Andover, Sept. 11th, 1834.

From Featherstonhaugh's Geological Report.

IMPORTANCE OF GEOLOGICAL PRINCIPLES TO MINING OPERATIONS.

It may also be instructive to observe here that the eastern coal field of the southern states, with which we are acquainted in Virginia and Alabama—in the former of which states it has already become a source of great wealth, giving constant employment to locomotive power and shipping—may reasonably be inferred, from some known partial indications, to be continuous between those points. I can confidently assert, from personal inspection, that there is a very promising line of continuity between those extreme points; and the bituminous coal, of a very fine quality, may reasonably be expected to be found in situations where it does not crop out on the surface. As an evidence of the confidence which may be placed in geological indications, I consider it important to mention, in a brief manner, a coal mining operation now conducting in England—and which had just been commenced during a visit I paid that country in 1826—upon the sole ground of an entire confidence placed in geological principles, and without any indication whatever of coal cropping out on the surface. A shaft was sunk at Monkwearmouth, near Sunderland, in the county of Durham through a group of calcareous rocks which were supposed, from the immutability which rocks are believed to preserve as to the order of superposition to each other, to overlie certain coal veins existing in the contiguous parts of the country. The shaft was sunk 344 feet beneath the surface before any coal was found; they then reached a small seam of one and a half inches in thickness. This occurred in 1831, after encountering incredible difficulties in stopping an influx of water that had frequently almost overpowered them. They proceeded to a depth of one thousand feet, when it became necessary to invest more capital in pumps of greater capacity, and this without meeting more coal. But the proprietors had confidence in their operations, and, amidst the loudly expressed doubts of many of their friends, persevered until, at a depth of 1,478 feet below the level of high water mark, they reached a very valuable seam of fine coal, and are actually now carrying their shaft to a depth of one thousand eight hundred feet, in order to reach a vein of coal long worked in other situations, and which they are confident will be found within that depth. This vein, when reached, will repay all the outlay of capital, and become a source of great wealth.

From a Dublin Paper.

IMPORTANT SCIENTIFIC DISCOVERY.—REFUSE OF COAL GAS.

The scientific researches of Messrs. Enderby have changed this useless, and indeed expensively encumbering material to the holders, (as they were prohibited from even throwing it away, under considerable penalties on account of its pernicious qualities in the river or its offensive ones in air) into a valuable commodity. The material by a simple process of purifying will be of most essential service where intense light is required. The light it gives is only to be surpassed in brilliancy where a stream of hydrogen and oxygen gas is in combustion upon lime, or phosphorous is burnt in oxygen. Such being the fact it will be found most valuable in the lighthouse, and save many a mariner from a watery grave. It is also equally applicable to street or factory lights. Its leading recommendations are these—first, its cost is about one-tenth of gas viz; a light equal to a large cockspur burner can be procured for eight hours, at an expense of three halfpence. Second no wick is required, the lamp requires nothing but replenishing the receiver. Third, it has no offensive smell while in a state of combustion. The lamp is made of tin or any other suitable metal and the material flows into a cup; a stream of air is admitted through the centre of the flame, and a double cone open at the apex is placed upon it and the light is regulated by a cock. In the absence of this arrangement, it will hardly keep in a state of ignition.

From the American Farmer.

SHEEP HUSBANDRY.

Ravensworth, March 25, 1834.

Dear Sir—I have thought it not impossible, that in the present depressed state of agriculture, the following estimate of the profits of a farm devoted exclusively to sheep, might be of service to some of your numerous readers. I am not, I think mistaken, in supposing, that at the price at which corn and wheat now sell, they cannot be advantageously cultivated on lands yielding less than fifteen bushels of the former, and eight bushels of the latter per acre. And yet how many thousand of acres, both in Virginia and Maryland, are either thus employed at an expense very far exceeding their production, or are abandoned as wholly unfit for any agricultural purpose whatever!

My own experience has satisfied me that lands of this description, even of the poorest quality, may (if broken and tolerably well watered,) be advantageously converted into sheep-walks; and by a judicious course of husbandry, be made not only to produce a fair interest on the capital invested, but to furnish within themselves ample resources for their own renovation. To point out the means of accomplishing this desirable change is the object of the following estimate.

Very respectfully, yours, &c.

WM. H. FITZHUGH.

J. S. SKINNER, ESQ.

Estimate for a Farm devoted exclusively to Sheep.

A farm, containing 1000 acres of land, under a good fence, having a dwelling house and all necessary out houses, together with two milch cows, two work horses, (or four oxen,) two breeding sows, one thousand sheep, a light wagon, cart, gear, ploughs, harrows, hoes, spades, axes, and all other necessary utensils, may very readily be purchased in convenient locations, either in Maryland or Virginia for $12,000; which if it yields only six per cent. on the purchase money, or $720 nett per annum, would be a more profitable and safe investment than can be made in any stock in the U. States. But it is susceptible of demonstration, that with tolerably judicious management, it may be made to yield nearly double that amount, and be itself annually improved in value.

The following is the system of management, which, after long experience, I have no hesitation in recommending.

The farm and every thing appertaining to it, except the sheep, being secured at the beginning of the year, the first operation should be to throw it into three divisions, viz: two fields for grazing, of 350 acres each, and one of 300 acres, comprising the woodland, garden, house lots, and about 100 acres of open land for cultivation and improvement. This arrangment and the necessary fences may be completed during the freezing and wet weather of January, February and March; while the dry and open weather of those months should be devoted to ploughing and harrowing about 40 acres of arable land; one-half of which may be sown in oats, for a crop, by the end of March, and the other half planted in corn between the 1st and 15th of April.

These operations being completed, there will be time enough before the corn requires cultivation, to plough, harrow, and sow down in oats, ten acres more of the arable land for the purpose of improvement, by folding the sheep and cattle in them during the summer and fall; after which, the chief occupation of the hands till harvest, will be the cultivation of the corn and attention to the sheep, which ought to be purchased and brought on the farm as early in May as possible, and together with the cattle be folded every night on the oat grounds prepared for them, in a pen containing about half an acre of land.

As this business of folding is to be the great source of improvement and profit on a sheep farm, it ought to be managed with the greatest care. No danger need be apprehended to the sheep either from dogs or disease, provided cattle be always folded in the same pen with them, and care be taken never to put them up till after sunset, and always to turn them out before sunrise. With a view to the rapid and permanent improvement of the soil, I consider the following the best possible mode of conducting this part of the system.

When the first fold is sufficiently manured, (which will be eight or ten days, the pen should be removed, the ground ploughed, harrowed, and sowed down in oats, and ruta baga turnips; and the same process be pursued with each succeeding fold, till the first of August; care being taken in the meantime to turn in all that portion of the land prepared for folding, on which the oats have ripened before the folds have reached them.

On the 1st of August, the sheep should be divided into two flocks—one containing the breeding ewes and stock weathers; the other consisting of the lambs and such old ewes and weathers as it may be desirable to prepare for market. At this time too, the folds should be brought back to the ground first penned and sowed in oats and turnips, which will now be covered with a fine growth, and be ready for a second penning. In performing this operation two pens must be employed for the two divisions of sheep; the lambs and the muttons being permitted to occupy each pen, in advance, about four days, and the main flock following for about the same time.

Lands thus prepared will be brought to the highest possible state of fertility. Such as are penned before the first of September, may be sowed down in turnips, for the use of the sheep during the winter and spring; and the subsequent penning of September, October, November and December may be put in rye, wheat, kale, Hanover turnips, or any thing that vegetates quickly, for spring grazing. A piece of the poorest land on my farm, treated in this way, (except that wheat as a crop, was substituted for turnips, oats, &c.) fattened me fifty of the best muttons I ever saw; yielded $22\frac{1}{2}$ bushels of wheat to the acre, and is at the end of three years, still covered with a fine coat of orchard grass.

We have now arrived at the period of the year in which the sheep are to be put into winter quarters. For this purpose, the fatted sheep ought to be sold off as soon as possible, the breeding ewes put to themselves in one of the grazing fields, and the rest of the flock in the other. Each parcel should be brought up at night into a small lot near the house, provided with uniform shelters, and there fed both night and morning, on hay, corn tops, blades, or turnips. As the ewes begin to yean, which ought to be in March, they should be separated, or permitted to run on the ground prepared for them during the preceding fall; and their condition will be very much improved at this time by feeding them night and morning with oats in the straw, cut up to a proper degree of fineness.

The operations of the next and every subsequent year, will differ from the first only in this, that instead of breaking up new ground for an oat crop, oats may always be put in the twenty acres of corn land and the ten acres of manured land of the preceeding year; and the last should always be sowed down at the same time in orchard grass and clover. Ten acres of highly improved grass land would thus be added every year to the resources of the farm, until at length its quantity would probably justify the introduction of a few choice brood mares, as another source of profit, on the farm.

When the hundred acres first reserved for cultivation, shall, by this process, be converted into grass land, a farther encroachment, to the extent of fifty acres, may be made on each of the grazing fields, the same course of husbandry be pursued on them as on the first division.

The only permanent laborers requisite for such a farm as this, would be a man, his wife, and a boy old enough to plough. In shearing time and harvest, it might be necessary, perhaps, to employ additional labor.

The above system is adapted to the poorest description of high and broken lands in our country, and may be applied to a farm of any size, from two hundred to some thousand acres. I have now five farms, stocked with from two to five hundred sheep each, undergoing this process; and after experience of many years, and even at the present low price of wool, I have no disposition to change my system.

The following I consider a fair estimate of the product, expenditure and profits, of a farm of 1000 acres, thus cultivated.

Product. To be used on the Farm.

20 acres of corn manured in the hill, at 3 barrels per acre,	60 bbls.
20 acres of unimproved land in oats, at 5 bushels per acre,	100 bush.
10 acres of manured land in oats, at 20 bushels per acre,	200 bush.
5 acres of turnips, at 200 bushels per acre,	1000 bush.
Hay, veal, hogs, &c. &c.	

For Sale.

The wool of 1000 sheep, estimated at 4 lbs. (in the dirt,) per head,	4000 lbs.
An increase of 400 head of sheep, after making allowance for casualties, the use of the farm, &c.	400 head.

Supposing every thing made on the farm, except the wool and the increase of the sheep, to be consumed, we shall have for sale—

4000 lbs. of wool in the dirt, at 25 cents per lb.—equal to,	$1000
400 lambs and muttons, at $1 50 per head,	600
Gross sales,	$1600

From which deduct—

For permanent and occasional labor,	$200	
For contingencies,	200	
		400
Nett profit,		$1200

Being ten per cent. on the original investment. I will only add that this amount might, of course, be very much increased, by improving the quality of the wool.

W. H. F.

From the Tennessee Farmer.

USE OF TOADS OR FROGS TO DESTROY BUGS IN GARDENS.

On every square rod planted with cucumbers, put a piece of a board flat on the ground, to preserve your plants from a striped bug, which some seasons is very destructive. This simple experiment may seem to be novel and ineffectual; but the secret of the matter is, the board forms a shelter for a toad, which hops from under the cover at night and destroys the bugs, and during the day time may be found by turning over the board. Should any one have doubts on the subject, he can easily try the experiment.

Extract from A Guide to a course of Lectures on Geology, delivered in the University of Pennsylvania.

DESCRIPTION OF THE PRINCIPAL ROCKS, AND STATEMENTS OF THEIR COMPONENT PARTS.

By H. D. Rogers, Professor of Geology and Mineralogy.

The whole number of simple minerals is between 300 and 400; of these, however, a very small list will be found to comprise the ordinary materials of most rocks.

The following table embraces those minerals which occur, mingled together, most frequently in nature. They are given nearly in the order of their relative abundance, with the average quantity of the several metallic oxides, earths, &c. which enter into the composition of each.

TABLE OF MINERALS, &c.

	Silica	Alumina	Potash	Soda	Magnesia	Lime	Ox. of Iron	Ox. of mang	Fluoric acid	Water	
Quartz	99.00								1.00		
Feldspar	64.04	18.94	13.66				0.74				
Mica	46.14	26.16	10.12				8.17	0.61	1.09	2.00	
Hornblende	45.69	12.18			18.79	13.83	7.32	0.22	1.50		
Augite	54.86	0.21			16.49	23.67	4.44	0.42			
Hypersthene	54.25	2.25			14.00	1.50	24.50			1.	
Serpentine	42.50	1.00			38.63	0.25	1.50	1.62		15.20	Chrome 1.25.
Diallage	47.20	3.70			24.40	13.10	7.40			3.20	
Schorl	36.03	35.82	0.71	1.96	4.44	0.28	13.71	1.62			Boracic acid 3.49.
Chlorite	27.43	17.90	1.56		14.56	0.50	30.63			6.92	
Talc	56.90	0.80			26.40	4.00	8.10			3.00	
Garnet	39.69	20.19				1.01	35.99	3.09			
Steatite	61.68	0.83			27.80	0.25	2.50			6.00	
Actynolite	50.00	0.75	0.50		19.75	9.75	11.00	0.50		5.00	
Green sand	50.00	7.00	10.00				21.00			11.00	

Carbonate of lime.—Lime 56.00, carbonic acid 44.00.

Carbonate of magnesia.—Magnesia 48.00, carbonic acid 49, water 3.00.

Sulphate of lime.—Lime 32.00, sulphuric acid 46.00, water 22.00.

Muriate of soda.—Soda 53.44, muriatic acid 46.55.

Oxide of iron.—Iron, oxygen.

Sulphuret of iron.—Iron 47.85, Sulphur 52.15.

Descriptions of the above Minerals.

Feldspar.—Its colors are various, but it possesses a peculiar lustre, and a foliated structure, which distinguish it easily from other minerals. Occurs massive, disseminated and crystallized. Its common crystallized form, a broad six-sided prism, with dihædral summits; an oblique four-sided prism; a six-sided prism, terminated by five unequal faces. Structure foliated; cleavage in two directions; lustre shining, often pearly; translucent or nearly opaque; cross fracture conchoidal; fragments rhomboidal. Scratches glass. Before the blowpipe, on charcoal, in a bright heat, it turns glassy, whitish, semi-transparent, and melts on the edges into a translucent, frothy enamel, with great difficulty. With borax, fuses slowly into a clear glass. With solution of cobalt, gains a blue color on the fused edges. Specific gravity 2.54. Abundant in the gneiss rock near Philadelphia.

Mica.—Characterized by the readiness with which it splits into extremely thin, smooth, shining plates or scales, which are transparent, flexible, and highly elastic. Occurs abundantly disseminated in grains or spangles, also in masses, and sometimes in regular six-sided tables. Colors various; lustre shining, often pseudo-metallic. It is scratched by the knife, but the edges scratch glass; smooth but not unctuous. Different micas differ in their behavior before the blowpipe; generally they are fusible into a gray enamel, but with difficulty. Specific gravity 2.7. Abundant in the mica slate a few miles up the Schuylkill, also in the rock at Fairmount; beautiful masses occur near Wilmington.

Hornblende.—Color dark bottle green, passing into black; occurs massive, also sometimes in six-sided prismatic crystals; fracture crystalline, showing fibres confusedly aggregated; opaque when black; translucent on the edges when green; lustre shining, pearly; powder or streak, green; exhales a bitter smell when moistened. Before the blowpipe, melts with great ease into a blackish colored glass. Specific gravity 3.15 to 3.38. Found on the Schuylkill, not far from Fairmount.

Augite.—Prevailing color dark green, sometimes blackish or yellowish green; also brownish, gray, or even white. Massive, crystallized, and in grains. When regular, in six or eight-sided prisms, terminated at each extremity by two faces. Structure foliated. Lustre glimmering or splendent. Before the blowpipe, melts into a black enamel, with extreme difficulty, and only in minute proportions; this property distinguishes it from hornblende, which it much resembles in appearance. Specific gravity 3.15 to 3.57. Found a few miles from Baltimore.

Hypersthene.—Dark greenish brown or black, with pseudo-metallic reflections of a copper red; massive; structure lamellar; opaque. Powder dark greenish gray; yields slightly to the knife; scratches glass. Before the blowpipe, on charcoal, fuses easily into a grayish green opaque glass. Melts easily with borax into a dark green glass. Specific gravity 3.4. Found on Brandywine creek, Delaware.

Serpentine.—Common serpentine is usually classed as a simple mineral, though the composition of the rock which receives this name is by no means definite and uniform. Colors green, yellowish green, blackish green, brown, bluish gray, or reddish, variegated with stripes, veins and blotches; generally opaque and dull. Massive; fracture uneven, or splintery; hardness extremely variable; often gives out the odor of clay when breathed on. Heated in a flask, it gives off water and turns black. On charcoal, turns white, and in a good heat, melts on the thin edges into an enamel. With borax, slowly melts into a clear green colored glass. Gives a red color when fused with solution of cobalt. Specific gravity, 2.5. Bare Hills, near Baltimore; Hoboken, New Jersey; West Chester and Montgomery county at Easton, Penn.

Diallage.—Of this mineral there are two species; the *metalloidal* is however, the commonest as an ingredient in rocks. It is sometimes called Schiller spar; its colors are bottle emerald or olive green, yellowish or pinchback brown. Lustre approaching to semi-metallic. In granular concretions. Lamellar. Opaque in mass, but transparent in leaves. When turned towards the light, the colors suddenly appear and disappear, as in Labrador felspar. In the flask or matrass, yields water, crackles, and acquires a clearer color. Before the blowpipe, on charcoal, melts slowly on the edges into a gray scoria. With borax, melts with much difficulty into a transparent glass, somewhat tinged. Some variety infusible before the blowpipe. Specific gravity 3.1. Commonly found in serpentine. Found near Haverstraw Bay, New York.

Schorl.—Color velvet or brownish black. Massive and crystallized in three, six or nine-sided prisms, variously bevelled and striated. Lustre glistening, vitreous; brittle; fracture conchoidal; becomes elastic when heated. Before the blowpipe, fuses by itself into a frothy mass, and turns white; afterwards melts with difficulty into a translucent grayish yellow bead. With borax, melts readily with effervescence, into a nearly colorless and transparent glass. Specific gravity 3. Schorl resembles hornblende, but has a vitreous lustre, a conchoidal or uneven fracture and is electric while hornblende has a shining, rather pearly lustre, is softer, has a splintery fracture, a lamillated structure, and is non electric. Found near Baltimore, Rhinebeck, N. Y. In the gneiss rock near Philadelphia, at Judge Peters' quarry above the upper bridge—fine specimens 8 miles on the West Chester road.

Chlorite.—Green is the prevailing color, varying from dark green to light grayish green, and generally dull; massive, crystallized, in minute hexagonal scales and earthy. Opaque, lustre, shining, pearly, soft, unctious; of a darker green than talc or epidote. Before the blowpipe on charcoal it melts into a black globule, with a dull surface; with boron forms a dark green glass, does not fuse or froth with soda. Specific gravity, 2.6 to 2.9.

Chlorite Slate has nearly the same color, with a slaty or foliated structure, composed of minute scales, less unctuous than talc slate, and more unctuous than mica slate. Harper's Ferry; Charleston, near Boston; near the Falls of the Schuylkill, in hornblende rock, with quartz at Willow Grove, and laminated near the soap-stone quarry, east side of the Schuylkill.

Talc.—Colors, various shades of green or greenish white, and silvery white, massive in thin plates or scales, easily separated; also indurated, and in hexagonal plates; flexible, but not elastic; lustre shining, pearly; soft, easily cut; very unctuous, gives a pearly white streak when rubbed on paper. Before the blowpipe, talc generally turns white, but does not fuse, the laminæ separate; with borax it melts with effervescence into a greenish transparent glass. Mica is flexible and elastic; talc is flexible, but not elastic. Specific gravity, 2.8. On the Schuylkill about ten miles from Philadelphia, in the soap-stone quarries, with rhombic spar, also near Baltimore.

Steatite, sometimes confounded with soap-stone, but improperly. Colors, various dull shades of green pale gray, yellow and red; gray is the most common, translucent on the edges, massive forming large beds; fracture ragged or uneven, with marks of confused crystallization, translucent on the edges; unctuous, can be cut with a knife, very soft when first taken from the quarry, yields to the nail. Before the blowpipe, hardens and turns black, but it is not fusible. Specific gravity, 2.7 to 2.5.

Soap-stone much resembles steatite; is much softer, being some times kneaded like dough when first quarried; it also fuses into a white and somewhat translucent enamel. On the Schuylkill, ten miles above Philiadelphia, connected with talc—extensively quarried under the name of soap-stone; also abundant in Connecticut, at Somers.

Garnet occurs in granular masses, and in roundish crystals, with 12, 24 or 36 sides; color reddish or blackish brown, opaque or semi-transparent; lustre glistening; brittle; fracture uneven; before the blowpipe, fuses with some difficulty into a blackish or greenish globule; with borax forms a glass colored green by the iron present; froths strongly when fused. Specific gravity, 3.69 to 3.76. At Haddam, Con. on the east side of Wissahickon creek, also 1½ miles above the falls of Schuylkill, in mica slate.

Actynolite.—Colors, green, sometimes deep and beautiful; also dark green and brownish. Occurs in wedge-shaped concretions and four-sided flattened prisms, often deeply striated, brittle, fracture fibrous; singularly harsh to the touch; lustre highly shining, silky; translucent; scratches glass. On the first application of heat it turns deep brown, afterwards melts into a greenish gray glass. Its color will distinguish it from hornblende, which it much resembles in form. Epidote is of a lighter or more yellowish green. Near Baltimore, in all its varieties; at Concord in Pennsylvania, in large masses; on the Wissahickon, ten miles from Philadelphia, in green needle-shaped crystals, in steatite.

Carbonate of Lime.—The forms and external appearance of this mineral, are extremely various. Its prevailing color, however, is white, or grayish white; it occurs compact, massive, granular, crystalline; its fragments are generally rhomboidal; cleaves readily by the knife in the direction of the natural joints, forming rhombs, with smooth polished faces, transparent or translucent; cross fracture uneven, but difficult to be obtained, from the ease with which it divides at the natural joints, scratched by the knife. Heated alone in the flask or matrass, yields no moisture. Before the blowpipe, on charcoal, infuses, if ture; does not tinge the flame, but glows with peculiar brightness when the carbonic acid has been driven off. Loses by complete calcination about 43 per cent.—becomes caustic, heats with water, and acts as an alkali. Effervesces when dropped in acids. Specific gravity 2.7. Its localities are extremely numerous. Some beautiful varieties are found at Lockport, New York.

Carbonate of Magnesia.—The crystallized variety is white, in delicate needle-shaped crystals, diverging and having the lustre of satin. The compact variety is gray or yellowish; either irregular or sponge-shaped; a splintery or a flat conchoidal fracture nearly opaque; yields to the nail; adheres to the tongue; dissolves slowly in sulphuric acid with effervescence. Before the blowpipe, infusible, but hardens so as to scratch glass—it then acts on moistened turmeric paper, like an alkali. Specific gravity 2.7. Occurs frequently combined with carbonate of lime. Bare Hills, near Baltimore.

Sulphate of Lime.—Gypsum, occurs massive, crystallized, granular, fibrous and compact; prevailing color white; sometimes gray, yellowish and reddish. Crystals flat, or six or eight-sided prisms, but oblique terminations; cleave easily into laminæ, which are flexible but not elastic; lustre shining, pearly; very soft; yields to the nail; frequently colorless and highly transparent. In the matrass, alone, gives off water, and becomes milky white, if pure. Melts into an enamel. On charcoal decomposes in the inner flame, after which it acts like an alkali. With borax, effervesces, and melts into a clear glass of a brownish yellow color when cold. Specific gravity 2.3. Nova Scotia, Niagara and west of New York; found also in the Jersey marl.

Muriate of Soda.—Common table salt is too well known to require description. As native rock salt, it occurs in great quantities beyond the Rocky Mountains, and exists in a state of solution in inexhaustible quantities in the formations of the western states.

Green Sand.—Color, various shades of green, from pretty bright grass green to deep olive green, and almost to greenish black: it has sometimes a dull greenish blue shade. Occurs in loose grains, about the coarseness of gunpowder, which the darker kinds much resemble. When very moist, can be kneaded between the fingers. Between the teeth has the sensation and taste of clay. Found sometimes alone in extensive beds, at others mingled in the loose slate with ordinary sand and mica; is disseminated through the substance of various limestone and sandstone rocks. It constitutes the green marl of New Jersey, and is found extending from that state, south through a great range of country, and far west upon the Missouri.

Oxide of Iron.—The various iron ores are generally too well known to require description here.

Sulphuret of Iron.—Color, brass yellow, passing into steel gray. Occurs in many regular crystalline forms, but more usually in that of the cube also irregular, brittle: fracture granular; lustre metallic, brilliant; too hard to yield to the knife, which distinguishes it from sulphuret of copper, which yields readily to the knife. Heated in the fire or in an open tube, it exhales the smell of sulphur. Is often mistaken by the ignorant for gold, but its great hardness immediately distinguishes the two. Specific gravity 4.7.

From Communications to the Board of Agriculture.

OBSERVATIONS ON THE UNITED STATES OF AMERICA.

By William Strickland, Esq. of Yorkshire. Received 8th March, 1796.

Mr. Strickland, having been favored with some queries from the Board of Agriculture, before his late visit to the United States of America, in which were pointed out objects of inquiry, connected with the institution of the Board, and particularly deserving his attention, takes the liberty of returning the following answers to them. He is satisfied that they are by no means complete, nor as worthy of the inspection of the Board as he could have wished them to have been; he hopes, however, that the imperfections will prove to arise rather from having omitted much, than from having stated that which is inaccurate; and that it will be considered, that his residence in that country was short, the country very extensive, and that other objects demanding his chief attention, might be very numerous.

York, Feb. 27th, 1796.

"What is the price of land?"

In taking an agricultural survey of the United States of America, our inquiries are rendered more easy in one instance, than they would be, in that of any other country, from the circumstance of one superficial measure only, being there made use of, the statute acre of England. As far as I could find, no other measure is known or referred to; but in other instances, the result will prove very different; in Europe, and in England particularly, mere locality occasionally excepted, the quality of the soil has the chief influence on the price, and will in every country effect it, in proportion as agriculture is well understood. In Europe, the produce of the land is the object of the purchaser, or the rent, which to the owner, is the same thing; in America, quality of soil has little influence on the price; for there, agricultural knowledge in general is at the lowest ebb; for unless the land be actually incapable of producing any thing from being mountain or swamp, the quality of it is little considered in the purchase. This circumstance I should have been apt to have attributed to the great variety of produce cultivated in the country, in consequence of which every variety of land would be applicable to some of them, had I not observed the same uniformity of price, where the kind of articles cultivated was much more limited. In America, the price of the land is chiefly affected by the vicinity of easy conveyance of the produce, or of the great towns on the Atlantic, the chief seats of consumption and export; but the situation of it on navigable waters has always a greater tendency to increase the price, than distance from the coast has to depress it.

One other very essential difference is also to be pointed out; in Europe, rent must ever be connected with price, and that is influenced by the quality of soil; in America, rent is never thought of, for land is very rarely let; what instances of it have occurred, and what information I could procure respecting it, I shall hereafter state; but first, I shall proceed to the price; and with that view commence with Massachusetts, Rhode Island, and Connecticut. These states, being in so many instances circumstanced alike, having no *backlands*, as called, that is, lands lately taken up or settled; being all situated on the sea; all of the same early foundation: covered with an uniform and abundant population; inhabited by the same unmixed race; governed by the same laws, principles, and customs; actuated by the same spirit of order, industry, economy, and enterprize, may properly be taken together, under the general name of

NEW ENGLAND.

This is universally an hilly country, of irregular surface, very rocky, in most parts great masses of stone lying on the surface, or starting abruptly from it, but no where what may be termed mountainous; the green-woods, [green-mountains] as they are called, running along the western extremity of it, and which are part of that chain of mountains which traverse the continent of North America, in the north-east and south-west directions, are here of no very great height, and would, I believe, admit of cultivation in almost every part of them; certainly where I crossed them in the north-west part of Massachusetts, where they by no means come under the description of mountains. The soil of New England has in general a tendency to clay, variously mixed with sand and loam, but nothing of a calcareous quality is known in any part of it.

The country is chiefly applied to the breeding and grazing of cattle and sheep; for which, from the verdure, and great inclination to produce herbage, it appears to be particularly calculated. No great quantity of grain is grown; I believe not sufficient for the maintenance of the people; so that in general the consumption demands import, certainly never admits of export.

All along the coast of New England, as far north as Boston, land sells on an average by the farm at from £3* to £3 15s. per acre, and is eagerly sought after at that price; much of this land is not of a good quality, and all of it greatly exposed to the influence of the sea. About Boston the price is considerably higher, particularly if near the town; a gentleman residing there, has an estate within three miles, consisting of three hundred and eighty acres, divided into two farms, which he has great difficulty in letting, and then only for £52 10s. per annum of which he does not receive more than £30, the rest being laid out in improvements and cultivation; besides which, he partly stocks the farms, having twenty cows upon them, his property. Supposing the land to be worth £3 15s. per acre, this estate,

* I have throughout reduced the various denominations of money met with in the United States, and the various currencies of the different states, to sterling; in larger sums, omitting minute fractions, but inserting them where their relative proportion to the sum could be of any material value.

cows included, does not net more than two per cent.

No person here will rent land.

About Dudley, land sells at £6 per acre, and upwards.

About Hartford, it will not produce more than three and a half per cent., and it is difficult to let it at that rate. A gentleman there, eight years since, gave £4 10s. per acre for some wood land and has since been offered £9 per acre for the wood only; timber and wood having doubled in price, in every part of New England, within ten years.

Very good land about the town of Springfield, will let, so as to produce five per cent. About Northampton, land, on the banks of the Connecticut, of most excellent quality, fit for every purpose of pasturage or cultivation, would sell for £5 5s. or £6 per acre; in favorable years this land would produce as high as twenty bushels of wheat, per acre, but more commonly produces fifteen or sixteen. About Chesterfield, land will sell according to situation, from £2 5s. to £4 10s. per acre. Here I saw a farm of one hundred and eighty acres, which three years since cost £135 in a very rocky, steep, and wet situation, but very abundant in grass.

Here, therefore, the average price is £4 per acre, and pretty uniformly declines as it is situated more inland, except in the instance of the range along the coast, the price of which may probably be lessened by its exposure to the sea; and the land appears to pay about three and a half per cent. interest.

NEW YORK.

This being the state in which the greatest land speculations take place, and to which the emigrants from Europe, who have any property, chiefly turn their attention, which from climate, the cheapness and plenty of land, the convenience of transport, the nature of the government, and laws and manners of the people, seems to hold out the most favorable circumstances for settlement, it will require to be particularly examined. In the immense range of country in the west part of this state, land may be got on very low terms; much of it is yet barely known, and much of it is either yet *unlocated*, or if *located*, only by those land jobbers who have purchased from the government of the state, vast tracts at very low prices, with a view to sell them again as soon as population should approach their districts.

The lower part of this state much resembles the country last described, being rocky and uneven, but in most places admitting of cultivation. About fifty miles from the coast, the country is traversed by the before mentioned range of hills, called, properly enough, the Highlands of New York; they are of considerable but unascertained height, probably about one thousand, or one thousand two hundred feet, and in many parts are entirely covered with woods, and apparently never will admit of cultivation, and may extend in breadth about fifty miles; beyond them is a fertile, beautiful, irregular country, extending to Albany, and thence back many miles to the country now only beginning to be settled. The soil much resembles that of New England, and has nothing of a calcareous quality known in it. This is the granary of North America; and a great quantity of wheat is now brought to Albany, from at least an hundred miles beyond it, grown on the banks and branches of the river Mohawk.

From the state of New York, many parts of the continent are supplied with grain; and from the city of New York, and the ports on the river Hudson, more grain and flour are exported, than from any other port in the union, except perhaps Philadelphia. Here also grain is cheaper on an average than elsewhere, according to the present price, by at least sixpence per bushel.

Fields within two miles of New York will let for from £2 14s. to £3 7s. 6d. per acre, to gardeners, &c.; in some instances I am told at still higher prices. An estate within and joining to New York, bought five years since for £1575, was sold in the summer of 1794 for £7312 10s. and was (in September, 1794) again selling in lots for building upon, and the purchaser expected to clear a very large sum. Another estate near New York, confiscated during the war, was purchased about seventy years since for £956 and sold lately for £112,500.

Phillips's Manor, which was likewise confiscated, was sold by the state for various prices, from 11s. 3d. to £5 12s. 6d. per acre; no average for the whole can be drawn, some of it being incapable of cultivation. Near Mount Pleasant, £393 15s. was asked for ninety-six acres, of which thirty were wood, with a good new house upon it worth £56 5s. or per acre £3 10s. Near Peckskill, a farm of four hundred and forty acres, one hundred of which were cleared land on a stream in a valley, the rest wood on mountains, not much of which was capable of cultivation, but in the woods sixty head of cattle might be maintained, would let for £14 per annum, and the price asked for it was £393 15s. or per acre 17s. 10d.

A farm near Kings Ferry, of two hundred and forty acres highly cultivated, well planted with fruit trees, in their prime, a good house upon it, with every thing in good condition, lately sold for £3375 or per acre £14 2s.; but then a convenient situation for trade added greatly to the price.

At Fishkill, a farm of one hundred and forty acres cost £223 15s. or per acre £2 6s. 3d. Close to the town of Poughkepsie, land sold at £28 2s. 6d. per acre, in small quantities.

Near Clermont, an English gentleman purchased five hundred acres for £2812 with a good house upon it, which was reckoned in the purchase at £562 10s. every thing in excellent condition, one hundred and fifty acres of it containing very fine timber, and the whole lying on the Hudson, or per acre £4 11s. This was reckoned a good purchase.

At Stephen-town, about twenty miles from Albany, and as many from water carriage, land sells at from £2 5s. to £2 16s. per acre. A gentleman in Albany bought a farm near that place, in 1789, for £22 10s. which he has since sold for £393 15s. and supposes it now worth double that sum.

Many tracts in all this country to the westward, bought within these few years, have since been sold for ten-fold profit; and in small tracts for much more.

An estate of one thousand acres, two hundred and fifty of which are best *river side* land, the rest pine land, but level and capable of cultivation, and some already cultivated on the Mohawk, opposite Schenectady, beautifully situated, with an house upon it, estimated in the purchase at £562 10s. is to be sold for £5625; or per acre about £5.

An extensive patent of excellent land, on the Mohawk, belonging to an English nobleman, was lately sold for less than 4s. 6d. per acre; while ten thousand acres very near it, through which the river ran, and which was sold four years since for 7s. 10½d. per acre, was at the same time again upon sale, and the price asked for it £1 2s. 6d. Many men of family and fortune in England possess large tracts in this state, and the land speculators of the country are particularly eager of dealing with them.

A gentleman gave, in 1791, £22 10s. for six hundred acres of soldiers' grants, and sold them, in 1794, for £331 10s. or 11s. per acre. A few years after the peace, he gave £16 17s. 6d. for one thousand acres in Jellisfonda, which he sold in November, 1794, for £393 15s. or per acre 7s. 10d.

Land at Konondaigua, on Seneka lake, which in 1789 would scarcely sell for 5d. per acre, two years afterwards sold for 2s. 9d.; four years after for 6s. 2d.; and I saw some of it sold in 1794, by public auction, in tracts of three hundred acres and upwards, for 8s.

A gentleman bought a tract of land in 1792, at Konondaigua for 2s. 3d. per acre, which in November, 1794, he sold for 9s. to one who purchased it to sell again.

A gentleman of rank in England, about the year 1790, purchased one million of acres on lake Ontario, in what is called the Chenesse country, for about 1s. 10d. per acre, which would in November, 1794, fetch from 4s. 6d. to 5s. 6d. when sold in large tracts of one thousand acres or upwards, and about 13s. 6d. when sold to settlers in smaller parcels, who have ten years credit; paying interest at the rate of seven per cent. during part of the time, or who purchase on some such terms, according to agreement.

A person of Hudson, had a large tract on the west of Lake Seneka, which he bought of the state in 1787, at 7½d. per acre, and which, December, 1794, sold for 6s. 9d. to a speculator to sell again. This land lies the farthest west of any I have yet heard of, being sold in this state; beyond it, the country is scarce known.

A person residing in Upper Canada, has a *township* of land consisting of one hundred and thirty thousand acres, at the junction of the Oswegatchi and the St. Lawrence, for which he was offered in January, 1794, 7½d. per acre, having put it up to sale at New York, to see whether it was at that time of any value; but many people having removed into that country, in the course of the summer, he was offered, in December, 1794, 4s. 6d. per acre for it.

Hence the average price of land, in the old settled country below Schenectady, (rejecting such as being mountainous is little capable of cultivation, and such as for mercantile purposes, or from being in the vicinity of large towns, is of increased value) appears to be £3 7s. 10d. per acre, and of the new settled country to the west of it, 9s. 3¾d.

So little land is rented in this state, except in the vicinity of towns, that there are no grounds on which to state the interest paid by purchases; I suspect, however, that it no where exceeds three and a half per cent.; but considerable tracts of land in the old Dutch patents, are what is here called, but improperly, rented; being granted out on leases for three lives, renewable on certain immutable terms, or on very long leases, or leases for ever, with a certain reserved rent usually in wheat, as from fifteen to twenty bushels per hundred acres, with various feudal services and payments annexed, of varying and uncertain value; but these do not afford sufficient data, on which to calculate the rent or interest. Proprietors of lands in this state are still in the habits of granting them out on similar terms.

NEW JERSEY AND PENNSYLVANIA

May very properly be taken together, the former appearing, as it were, part of the latter, extending eastward towards the sea; great part of it is a low, flat, sandy, wet unhealthy country, little frequented, and less cultivated. Inland of this tract in Jersey and Pennsylvania, is a dry, rising, irregular country consisting chiefly of what is here called isinglass land, a sandy soil full of micaceous particles, glimmer, and talc; from which the surface of the country, while the sun is shining, acquires a singular appearance; most of the remainder is a deep red loam approaching to clay, and which probably would have most of the properties of it, in a climate where there was more wet and less sun, is of great fertility, and capable, by proper cultivation, of producing every thing of which the climate will admit.

This country continues, with considerable variations in parts, to the chain of mountains which traverse the two states. These mountains are chiefly composed of micaceous granite, in some places on a limestone or marble base; they run in parallel ribs of great height,* and are in general very barren, and covered in many parts with shrubs and trees of humble growth, but divided by extensive and fruitful vallies, and may extend in breadth about sixty or eighty miles. Beyond them to the west is a vast tract of country, said to be fertile and fine, but not much known; and though the whole of it may perhaps be held under patents from the state, it is hitherto very thinly inhabited, and the greatest part of it not at all. Lots in the town of Paterston in Jersey, of one-fourth of an acre, sell for £15.

Near Brunswick, an English gentleman gave, in the summer of 1795, £2100 for three hundred and thirty-four acres of excellent land, fit for every purpose of cultivation, or per acre £6 5s. This being also in an eligible situation in every respect, was thought a reasonable purchase. A gentleman has two thousand five hundred acres in Jersey, which he lets, though with some difficulty, since so few choose to rent land, in seven farms, at a rent which he thinks pays better than at £4

* The highest ridge of these mountains in New Jersey, near the banks of the river Hudson, has lately been ascertained to be about 3,500 feet in height, above the level of the tide in the river at their foot. (*Transactions of the Society of Agriculture of New York, Vol. I. Part, II. p. 139.*)

per cent. but from this some deductions are to be made. Building lots in the principal streets in Philadelphia, sell at £60 per foot in front, and are from one hundred to one hundred and eighty feet in depth; before I left Philadelphia, I heard of one being sold for £72 per foot in front.

Land upon the Delaware, and the navigable waters that run into it, sell in each state for from £4 16s. to £5 12s. 6d. At two or three miles from water-carriage, at £2 14s. to £3 3s. These last prices I have found to hold through the greatest part of the old settled tracts of Jersey and Pennsylvania, but something lower as the situations are less convenient.

About York, among the Germans, land sells as high as £15 to £18 per acre; in the neighborhood of Lancaster, from £12 to £15; near the town, for £18. I saw a considerable farm, one mile and a half distant from it, that had just then been purchased at the last price; water-meadow land will sell there for £21 per acre; the industry and parsimony of these people having raised the value of land in their neighborhood at least two hundred per cent.

The best land in Jersey, and in that part of Pennsylvania which is east of the mountains, exclusive of the German tract, may be settled at about £4 per acre: they certainly average something more than the old part of New York, this tract not being mixed with any barren mountains, and being less rocky and broken.

The back-lands of Pennsylvania sell for considerably less than those of New York: from what information I could obtain, I could not state them at more than 3s. or 4s. per acre; a great quantity was upon sale for less; the tenure of them is less satisfactory than of those of New York, the titles less to be relied upon, and the whole having less credit, many egregious frauds having been committed upon purchasers, particularly those in Europe.

Very little land is let, few of the people born in the country being ever willing to become tenants, and farmers from England, who alone would be tenants of any value, are very few in number, and those, as far as I can find, in general not of a very respectable description. Custom or ignorance can alone cause this objection; since they who purchase land purchase it with money that would otherwise afford them seven or eight per cent. at the least; whereas if they rented land, it would be at a rate that would not pay more to the owners of it, than an interest of three or four per cent.; a great gain this to the tenant, who would besides have many indulgencies. So great is the difficulty of procuring regular tenants, that people here, who possess more land than they choose to occupy, or can cultivate themselves, are getting much into the way of letting it upon shares; a system which nothing but extreme poverty, or extreme ignorance, can vindicate.

This evil is rapidly increasing; an instance of this tenure I have before noticed at Boston. I have not yet heard of any in New York; but in Jersey and Pennsylvania instances are too frequent; to the south of these states I have met with none.

A country thus occupied must ever be in the worst cultivation, and both owner and occupier in a state of poverty. The terms of this tenure are various, according as agreements can be made; in some instances, the owner finds half the seed, and half the live stock, the tenant every thing else; and he has half the produce; in other instances, the owners find half the live stock, and have one-third of the produce, &c.

Want of capital in tenants, the difficulty of procuring them, and their ignorance when procured, was the cause assigned for this wretched mode of occupation; but it was observed, that under this tenure, the owner could command the mode of cultivation; and that therefore, such lands were better cultivated than others: this, however, presumes the landlord to be more intelligent than his tenant. The extent of the evils arising from this mode of occupancy, many parts of Europe sufficiently show: wherever it is found, poverty, and the worst of cultivation attend it, as ever must be the case, where the interest of the owner and the occupier are at eternal variance; here, the owner purchases the worst of stock, because it is the cheapest, and another is to have the management of it; and the occupier bestows the least labor, because another is to have half the profit of it. It was scarcely to have been expected, that such a system should have crossed the Atlantic.

DELAWARE AND MARYLAND

May with propriety be joined together. The former is of small extent, and occupies only one-half of that peninsula which lies between the two great æstuaries of Delaware and Chesapeake, each side of which peninsula much resembles the other. The whole of Delaware, and the adjoining part of Maryland, is a low country, apparently the creation of waters. It has in general a tendency to sand, is not much elevated above the sea, is fertile upon the coast, but swampy and barren within land. That part of Maryland that lies upon the opposite side of the Chesapeake, is in general sandy and gravelly; in places elevated into hills generally barren; and much worn out with the cultivation of tobacco.

The farther it proceeds west, till it arrives at the mountains, the more fertile it becomes, is less sandy, and at last, about Frederick, changes to that rich, red, friable loam, before noticed in the last states, here generally lying upon a steatite or soap-rock, which in many places rises to the surface. These two states are the first in proceeding towards the south, in which negroes abound, and in which the evils of slavery first appear, though here laying no very heavy burden upon those who are doomed to bear it; and here, slavery is rapidly giving way to emancipation. This state has no *back-lands*, and no territory of any great value west of the mountains, as in that part the Potomac, its southern boundary, and the Pennsylvania line its northern, contract within a very narrow space.

As the metropolis of the American Union is now building in this state, and is to become the seat of government in the first year of the next century, a very considerable rise in the price of land, and some improvement in the cultivation, will probably soon take place.

About Dover, in Delaware, land sells for £3 12s. per acre. About Buck's tavern, £3 18s. One thousand seven hundred acres, a few miles below Wilmington, were lately sold at £4 per acre. An English gentleman lately bought some on the Delaware, at £7 4s. but it was supposed with mercantile views. A person has two hundred and fifty acres of excellent land near Middletown, for which he has been offered £6 per acre: he lets them for £90 per annum, and binds the tenant to cultivation, or per acre 7s. 2d.; they pay an interest of £5 19s. 5d. per cent. On Wye river, in Maryland, a gentleman has several thousand acres, that produce him from £18 to £24 per hundred acres, chiefly paid in wheat, or per acre 3s. 7d. to 4s. 9½d. As such land would sell on an average of £6 12s. per acre, it pays an interest of from £2 14s. 3½d. to £3 12s. 7d. £7 14s. per acre was lately offered for half an island in the Chesapeake, called Chew's Island, which contains above two thousand acres, and refused. On Bohemia river, average price of land is £4 16s. some as high as £7 10.; if good wood land, which is much sought after, for at least £9. About Perry Hall, the general average of the country is £3 6s. Three or four miles from Baltimore, land will sell for, from £15 to £18 per acre; and small lots, near the town, from £36 to £42.

Old worn out land, without timber, on the Patapsco, thirty miles from Baltimore, has lately been sold at 9s. per acre. A gentleman has land at the back of the new city of Washington, which forty-five years since, cost £25 per hundred acres, for which he has lately refused £30 per acre. About the upper falls of the Potomac, land, equal part of wood and clear, will sell for about £3 12s. per acre. Land on each side of the Monocacy, will fetch from £3 to £4 4s. per acre; a mile or two from Frederick, ten guineas; close to the town, £18.

From the above, and many other notes taken in the state, it appears, that land here, excluding as I have before done, whatever is of increased value from mercantile situations, or the vicinity of large towns, sells at £4 17s. per acre: a price considerably higher than is to be met with in any other state in the union; more land also is let, and the interest paid by it, is higher; the causes of which I shall hereafter assign, when the prices are recapitulated and collected. The result of various notes, proves the rent to be about 5s. per acre, and the interest paid by land, about four per cent.

VIRGINIA.

This immense country possesses every variety of soil and surface; below the falls of the rivers, that is, for the space of the tide-waters, which may extend from the coast about one hundred and twenty miles, the country is very flat, apparently of late ages risen out of the sea, in many parts abounding with extensive swamps. The soil is in general a fine white sand, except on the banks of the rivers, not fertile, and much of the natural produce is cedars and pines, always indications of a poor soil. The country in general is very unhealthy, infested with fever and ague, and bilious complaints, as may be expected from such a surface, in such a climate; and is much worn out, having been long settled, and the chief produce tobacco. Above this, is an irregular waving country, lying for the most part in ridges, gradually falling down to the nearest rivers on each side, and high in proportion to their distance: this tract, which may extend about eighty miles inland from the head of the tide, in its original state, has not been fertile except on the banks of the waters.

Beyond this to the foot of the *Blue Ridge*, across, and comprehending what are called the South-West Mountains, but which are only a range of hills, a step to the Blue Ridge, capable of cultivation in almost every part, is a tract of the same red land before noticed, as lying to the east of the mountains: it is here of its deepest red; deep as red ochre or chalk, and with its intensity of color, has acquired its utmost fertility. A richer district by nature there cannot be, than all those counties which lie at the eastern foot of the Blue Ridge; but, like whatever on this continent has been long cultivated, they are nearly exhausted. Beyond the Blue Ridge, and various other ridges lying west of it, and parallel to it, are extensive vallies, from five miles to thirty in width, the plains of which are highly elevated above the sea, but lying between mountains far more elevated. The soil of these vallies is calcareous, lying every where upon a limestone, or marble, the same as constitutes the basis of the mountains, which are themselves chiefly granite, quartz, and steatite. These vallies I traversed from Carolina to Pennsylvania, in June, 1795, with infinite pleasure: it is a delightful region, refreshed with frequent showers collected on the mountains, enjoying the ventilation and cool breezes of a northern climate, with the perpetual sunshine of a southern latitude.

In a state, the soil of which varies so greatly, in climates the most desirable, as well as the most noxious to the human frame, the value of property must differ in proportion; and that it does so, will appear in stating a few instances on each side of the mountains, and then the average of each.

On the lower part of the Rappahannock, on each side of it, land, on the banks, will sell for £1 11s. 6d.; at some distance from the river, from 18s. to £1 2s. 6d. On James River, below Richmond, £1 10s.; in a few very favorable situations as high as £4 10s.; upon James River, above the falls, at £4 10s. A few miles from the river £1 10s. and £2 5s. Upon the South-West Mountains, for no where more than £2 5s. The best red land in the counties of Orange, Albemarle, and Amherst, than which, none in nature is more fertile, or better adapted to clover and wheat, may be bought for 18s. per acre; I saw a considerable tract that had lately been purchased for 16s.

To the west of the Blue Ridge. Good land in Rockbridge county, sells for £4 10s. Land in general, including rocks and woods £1 10s. About Patten's ordinary,* for about £3 7s. 6d. A farm, at this place, was shown me by the proprietor, containing eleven hundred acres, one-third of it cleared, and somewhat cultivated, which he had lately purchased at £2 5s. per acre, which was thought very reasonable. (Immense tracts of all these mountains, of which one thousand acres would not be worth a shilling, and which have been neglected till within these two or three years, have been taken up by the land jobbers to sell, and are now sold, or selling in Europe.) About Newtown, most excellent land for pasturage will

* Inns or taverns in the country parts of Virginia, are called ordinaries.

sell for from £6 15s. to £7 10s. per acre. The average rate of land in the country about Winchester, from £2 5s. to £4 10s. in some instances, near the town, £7 10s. Upon the Shenandoah, the usual price is £1 11s. 6d.

To the west of the Allegany ridge, is a vast tract of back country in Virginia, lying upon the great Kanawha river, one of the branches of the Ohio, but little known, inhabited, or cultivated, and in which the lands sell at very low prices: forty thousand acres were, in the spring of 1795, advertised in a Philadelphia paper to be sold; the terms proposed, were 7d. per acre, one quarter to be paid in hand, and the rest in two equal annual payments; other vast tracts in Virginia and Kentucky were then also upon sale, the usual price asked for which was 1s. 1½d. per acre, with considerable time allowed for making the payments.

Average to the east of the Blue Ridge, £1 19s. 8d.; to the west of it £4 3s. 10d. As far as I know, no lands are let in Virginia; therefore, there are no means by which, with tolerable accuracy, to ascertain the rate of interest for money employed in the purchase of lands.

OF THE SOUTHERN STATES

I can give little account; in all of them the land sells at a very low rate, and lower as it lies farther south.

A merchant in Philadelphia, in the summer of 1795, purchased one hundred thousand acres of land in Georgia, beginning about four miles from Augusta, the capital of the state, and lying on the road to Savannah, at 4½d. per acre.

Could the interest be stated with equal accuracy, I should apprehend it would not produce much more than three per cent. when in the hands of the tenant, though the occupier and owner are equally exempt from the payment of almost any manner of tax; but very few will rent land, and none know how to cultivate it, as will be seen, when the rotation and produce of crops are noticed.

Before the Revolution, the laws established a legal interest; in some of the states, seven per cent. in others, eight per cent. and in the southern states, I believe, more. Since the Revolution, congress has never touched the subject of interest; and if the laws in the different states still remain in force, they are become obsolete; certainly no attention is paid to them, but every one makes the most advantage that he is able, of his money, as of any other commodity; and there are sufficient opportunities of making more than what was heretofore legal: this shows that land is little worthy of attention here, and accounts for emigrants from Europe, who, at first with European ideas, turn their attention to land, and wish to become proprietors of extensive estates, soon getting rid of their land, and employing their money on more productive speculations. Land in America affords little pleasure or profit, and appears in a progress of continually affording less; but it would take up too much room here, to state the foundations of these opinions.

Before I had collected, in one view, the particulars of every state, I should not have apprehended that Maryland, notwithstanding the favorable opinion I formed of it when there, in price, rent, and interest, would have stood first in the union. This state, in climate and produce. is more nearly allied to those on the south, than on the north of it; the climate is somewhat productive of those bilious habits and complaints, so dreadfully frequent immediately to the south of it; and, as in the south, the produce has hitherto been chiefly tobacco, which never was cultivated to the north; it has also ever abounded greatly in slaves; but it is more nearly allied to the northern states in its principles, and the liberality of its government; and to these and their consequences, this superiority must be ascribed. The body of the people may not be as well educated as those of New England, but they are fortunately uninfluenced by the wild theories of their southern neighbors: from hence it arises, that as men of property and education have the conduct of the government, it is carried on with the liberality that may be expected in such characters, and the best people of the country feel interested in the prosperity of it. Many persons of considerable opulence and extensive property reside on their estates, see to the cultivation of them, and diffuse knowledge, as far as they are informed themselves: more instances of this kind are to be met with in Maryland, than, perhaps, in any of the other states, and they have an influence of most beneficial tendency. To these causes I must attribute the superior value of property.

"What is the price of labor?"

September 1794. In the city of New York, seamen's wages were from £4 14s. to £4 19s.

per month: were at £4 1s. in the beginning of the summer, and at 36s. and 45s. before the war in Europe. A common laborer, as one to carry the hod, or help in clearing out a ship, 4s. 6d. per day. Carpenters, 5s. 7½d.: masons and bricklayers, 6s. 9d. and 7s. 3¾d.: all other mechanics and handicraftsmen, about 5s. 3d. These several last descriptions of people rarely work more than three days a week, as is usually the case with people of their class in other countries, where wages are too high.

July 1795. Seamen's wages were then risen to £6 15s. Nothing is allowed to laborers in New York city, except sometimes spirits to those who work on shipboard.

The average of the country in the state of New York, for agricultural labor, for six months from May-day, when hired by the month, 1s. 5d. per day; the other six months 1s. 1d.; if for less time, or by the day, 2s. may be reckoned the average of any part of the year. A foreman's wages £14 per annum; for mowing buckwheat, or other light mowing, 2s. 10d. per day; for cradling wheat, usually one bushel of wheat per day.

Exclusive of the above wages in money, every one in the country is provided with victuals, and in harvest expects at least a pint of rum, or other spirits, a day.

Wages appear to have risen, in this state, in the proportion of four to three, or thirty-three and one-third per cent. in the last three or four years.

NEW ENGLAND.

1794, autumn. Laborers by the month in summer per day, 2s.; by the month in winter, 1s. 3d.; if for a less time, or by the day, 2s. 7d. may be the average of any part of the year. Foreman in husbandry, or best working man, £18 15s. per annum. Laborers on the canal of the Connecticut, from 31s. 6d. to 40s. 6d. per month, according to abilities. Carpenters and handicraftsmen about 3s.: the wages in harvest are usually regulated by the price of maize, a bushel of which is allowed for a day's work; this year maize being high, wages are high likewise; 3s. per bushel, or per day; used to be 2s. 3d. All the above laborers, exclusive of their wages, are provided with victuals, and generally with cider to drink.

NEW JERSEY AND PENNSYLVANIA.

1794, winter. Wages in Philadelphia, much the same as in the city of New York. In the country, laborers by the month in summer per day, 2s.; by the month in winter per day, 1s. 9½d.; if for a less time, or by the day during any part of the year, 2s. 3d.; in hay time and harvest by the day, 3s. 5½d. Foreman £24 per annum. Laborers working by the piece at the Conawaga falls of Susquehannah, earn about 3s. per day, which is not too much, considering the unhealthiness of the place, and fatigue of the work.

At Elizabeth iron furnace, some of the head men have £90 per annum. All the common workmen, of which many are free blacks, have £21. All the above have their victuals found them, and in hay time and harvest the workmen expect, and drink at least their pint of rum, or other spirits, a day.

Aug. 1795. Seamen's wages, in Philadelphia, were as high as £7 17s. 6d. per month, and every ordinary seaman received it.

About the same rise of wages has taken place in these states, as elsewhere before noticed.

Somewhat less difference is paid here in wages, in winter and summer, than to the north, the climate admitting of more equal labor.

DELAWARE AND MARYLAND.

1795, summer. White laborers by the day, at any time of the year, 1s. 6d.; free blacks ditto, about 1s. Labor in harvest 4s. 6d. Free blacks by the year £8 8s.: hired slaves £7 4. Overseer, or head husbandman £22 10s. Laborers, on the canal of the Potomac, chiefly men who have worked on the canals in Great Britain, 36s. per month, board, and every necessary being likewise found them, except liquors. All the above have their victuals found them; the hired slaves are also clothed.

At the city of Washington, masons, 6s. to 7s. 2¼d. per day; carpenters, 4s. 9½d. to 6s.; negro laborers (hired slaves) 36s. per month, board and clothes.

Baltimore, mechanics, 6s. per day; common laborers, 4s. 6d.; seamen's wages £6 15s. per month.

Little difference in the rate of wages is made in these states, between winter and summer, the climate admitting of nearly equal labor throughout the year; nor does any rise appear to have taken place in them, except in Baltimore, where the demand for mechanical labor, in the construction of the new city of Washington, seems to have affected it considerably.

VIRGINIA.

Every thing here is performed by the labor of slaves, except on the west of the Blue Ridge, where they are not numerous; there the labor of the white people may be procured, during almost any part of the year, at about 2s. and their victuals; where slaves are doomed to toil, the freeman holds labor to be a degradation. Virginia is in a rapid decline, brought on by her adherence to so pernicious a regimen.

The value of slave labor I have taken considerable pains to investigate and prove, but have not been able to accomplish it to my satisfaction; it is the opinion universally received there, that it is much dearer than that of freemen; but I do not find, that any one in the country, where alone it could be ascertained, have ever undertaken the subject; some say it is more expensive by one-third, others by one-half; all agree in the fact, but none can fix the amount. The price, however, paid for the time of a slave can be easily established, and from that we must reason upon the value of his labor. Great numbers of slaves are hired out in this state by their owners, who may be overstocked, or may not have sufficient employment for them at the time; these are frequently hired by individuals, who are in want of their labor; or by the proprietors or undertakers of public works.

The usual price paid for a slave, employed in husbandry, is £9 per annum; he and his wife may be hired for £12; but the person that employs them also feeds and clothes them: several hundred were employed on the canal at the falls of James River, in the summer of 1795, all of whom were hired. As these were stout able men, they were paid for at the rate of £11 5s. each, per annum, and their maintenance* and clothing was calculated to amount to the same sum. Suppose, therefore, that the maintenance of the slave that is employed in husbandry, bears the same proportion to the price that is paid for his time; this will make the expense of such a person £18 per annum, or per day rather more than 1s. 2d. As the climate here, as in Maryland, admits of nearly equal labor throughout the year, it may be fair to estimate it at the same rate in each state; in Maryland, it appears that the service of free blacks may be had for about 1s. per day, and of whites for 1s. 6d.; therefore, the time of a slave, in Virginia, is estimated at somewhat an higher price, than that of a free black in Maryland, though at less than that of a white man. But the price that is paid for the *time*, is by no means a proof of the value of the *labor* of the slave; that can only be ascertained by the actual quantity performed, and the goodness when performed; and much more may be paid for it, than actually appears. Now, nothing can be conceived more inert than a slave; his unwilling labor is discovered in every step that he takes; he moves not if he can avoid it; if the eyes of the overseer be off him, he sleeps; the ox and the horse, driven by the slave, appear to sleep also; all is listless inactivity; all motion is evidently compulsory. Any slave, that I have seen at work, does not appear to perform half as much, as a laborer in England; nor does the business, under which the master sits down contented, appear to be half, that we require to be performed by one; if to this be added the slovenly carelessness with which all business is performed by the slave, the great number of useless hands the slave owner is obliged to maintain, the total indifference to, and neglect, not say the frequent willful destruction, of whatever is not immediately committed to his care, or within his department, and also the universal inclination to pilfering shown by them, I cannot do otherwise than acquiesce in the received opinion of the country, that slave labor is much dearer than any other; and that the price paid for the *time* of a slave, by no means shows the amount of *the value of his labor:* it certainly is much higher than it appears to be; though not knowing the quantity of labor, performed by slaves in general in a given time, in a sufficient number of instances, I have not data whereon to calculate the exact value.

RECAPITULATION.

	per day Labor in summer.		per day Labor in winter.	
In New England	2s.	0d.	1s.	3d.
New York	1	5	1	1
New Jersey and Pennsylvania	2	0	1	9½
Delaware and Maryland (white men)	1	6	1	6
Ditto free blacks, about	1	0	1	0
Virginia, perhaps equal to	2	0	2	0

The average of which will be 1s. 7¾d. in summer, and 1s. 5¼d. in winter; to this must be added the price of their victuals, which I find, in many instances in this country, is estimated at 9d. a day, except in hay time and harvest, when the workmen live something better, and have a larger allowance of spirits, or other liquors; this will raise the wages to something more than 2s. 4¾d. in summer, and 2s. 2¼d. in winter; but it is to be observed also, that as the sun sets three-quarters of an hour later, on the shortest day, at Philadelphia (which is about the centre of the union from north to south) than in London, and consequently rises as much earlier, three-quarters of an hour's labor is gained every day during the winter half year, which is a matter of no small consideration. Likewise, as it is the custom in America for all workmen, in the summer half year, to work from sunrise to sunset, and as the sun rises at Philadelphia at half past four on the longest day, an hour and a half before labor commences in England, and sets an hour and a half after it ceases, here is an additional gain of one hour and a half's labor during the other half year; from which no deductions are to be made, except that sometimes, in the very greatest heat of the weather, workmen are allowed to rest two hours in the middle of the day, instead of one as with us. This is a very great sum gained in the annual amount of labor, and leaves the difference of labor, between England and America, to stand thus:—the average of winter and summer, in America, 2s. 3½d.: average of labor in England, 1s. 4¾.: average of working hours in America, throughout the year, $12\frac{1}{16}$ hours; working hours in England, $10\frac{15}{16}$ hours; the latter hours paid by 1s. 4¾d. is to the former hours, as paid by 1s. 6½d.; therefore, were the wages in America 1s. 6½d. they would be the same as in England, but being 2s. 3½d. they are 9d. per day, or about one-fourth higher than wages were calculated to be in England, in the year 1793;* and the greatest part of this addition has only taken place within three or four years; before that time, wages were much alike in each country; and as wages, in England, are very considerably risen since the calculation in 1793, I ap-

* These men were allowed half a pound of pork each, a day, and three pounds of meal of Indian corn, which last is more than they can consume, with some other little occasional indulgencies; this was estimated extremely good keeping.

* See Young's France, Vol. I. p. 436.

prehend the wages, on each side of the Atlantic, are again nearly upon an equality; I suspect too, that in the climate of America, there will be fewer broken days in the year, or days entirely lost, than in England, where storms and long continued wet weather, either prevent labor, or render what is performed of little value. This refers only to agricultural labor; mechanical labor bears every where a much higher price; but with that I have nothing here to do.

The result of this inquiry is very different from what I expected, and from the generally received opinion; but, as it is a subject of so much consequence, I paid every attention to it; and it is the result of so many minutes, that I have little doubt of the accuracy of it: wherever any information was of a dubious nature, it was not at all noticed in this account. These wages are by no means of that unreasonable nature, that they should affect the prices of American produce, beyond what wages affect similar articles elsewhere; and it confirms also what I have generally heard, that in all the old settled country, there is no want of hands to perform the necessary demands of agriculture, particularly in a climate, in which wet or damps rarely occur, at a season when they would be injurious; or should they unseasonably occur, in which a brilliant sun would not soon take away their effects: this precludes the necessity of employing numerous hands; or of that expedition to which, in less favorable and more precarious climates, it necessarily is had recourse.

"To what circumstance is it owing, that eight bushels of wheat, raised by dear labor, are a profitable crop in the central states? the fact is curious."

With the answer to this question, the rotation and average of crops, the quantity of seed sown, and quality of the grain, are naturally connected. From the reply to the last query, it will be clear that agricultural labor is not dear, or at least not so dear as to have any material effect upon the price of the produce, beyond what labor will have in this country; nor perhaps ought it to have as much, since so little labor is bestowed upon it. As I have hitherto done, I shall divide the country into districts, according to the different descriptions and circumstances of it, and shall begin with

NEW ENGLAND.

This is a grazing country, and applicable to the rearing and feeding of cattle and sheep, producing herbage in abundance, and of excellent quality: no grain is ever exported from this district, and very little is raised in it except maize, on which, and on wheat imported from their neighbors at New York, the inhabitants chiefly depend. The plough is little resorted to, and consequently this district can afford no material information on the subject proposed; for that, we must look to

NEW YORK.

This state is undoubtedly the granary of America; and if America be, or is hereafter to be the granary of Europe, that must supply by her redundancy the wants of the latter, this must be the part that must do it.

The usual course of crops in this state, is as follows: first year, maize; second, rye or wheat, succeeded immediately by buckwheat, which stands for seed; third, flax or oats, or a mixed crop; then a repetition of the same, as long as the land will bear any thing; after which it is *laid by* without seed for *old-field:* or, *burn the woods;* first, wheat; second, rye; then maize for four or five years, or as long as it will grow; then *lay it by*, and begin on fresh woodland: or, burn the woods; wheat four or five years; then one or two maize, or as long as it will grow; then laid by for four or five years for old-field, without seed. A Dutchman's course on the Mohawk: first year, wheat; second, peas; third, wheat; fourth, oats or flax; fifth, maize: in his father's time, the produce of wheat used to be twenty bushels per acre; but he complained much, now that his land only produced ten bushels. The best rotation I met with, was in Dutchess county, where it much prevails: first, wheat; second and third, pasture without seed; fourth, maize, or flax, or oats, or mixed crop: in a good season this produced about fifteen bushels, more commonly twelve.

The land in this county has great inclination to produce grasses, the pasture being therefore good, and carrying, during the two years, a great stock; the succeeding crops are tolerably good also. Manure is rarely made use of; but what little is collected is given to the maize, which requires every support that can be bestowed upon it. Maize is sown early in the spring, and stands till October or November, growing most of the time with great vigor; in the early part of the growth, the plough is frequently used, going first along the furrows, and then crossing them in the contrary direction; and when it is grown too strong to admit an horse among it, hand hoeing is recurred to.

By so much cultivation, the whole strength of the land is thrown into this crop, which is one cause of the wheat being so deficient in quantity, and wheat, except in new land, every where follows maize; another is, the slovenly manner in which, in this succession, it must unavoidably be sown; the wheat is sprinkled among the maize immediately before the last hoeing; and as the land is thrown up in hillocks by the horse hoeing, the crop receives much damage from the weather in winter, as well as drought in summer.

Clover is just beginning to be cultivated, in consequence of which, good pasture and plenty of hay take place of *old-field*, and by the use of gypsum, astonishing crops are obtained.

A bushel of wheat or buckwheat per acre, is the usual quantity of seed; rarely either more or less, but as often one as the other. The average produce of wheat in the state of New York, has been stated to me by a very intelligent person, at twelve bushels to the acre; which agrees with the general opinion, and, I believe, is as high as it ought to be stated. The average of Dutchess county, which under proper cultivation would be a most productive, as it is a most beautiful, country, at sixteen bushels: twenty bushels are every where a great crop. The average of maize may be twenty-five bushels: above thirty is a great crop; that of buckwheat, which is very extensively cultivated, fifteen bushels. With a mode of agriculture, as before stated, it is not to be wondered at, that the produce should be so small; and it will be found that the average of this state, is superior to that of any other in the union.

How profit is to arise out of this, will now be seen; it has thus been calculated:

Rent or interest of capital, 4s. 6d.; one ploughing and harrowing, 5s. 7½d.; harvest, 4s. 6d.; seed, five pecks, 5s. 7½d.: total £1 0s. 3d. Straw pays for the thrashing. Twelve bushels, at 4s. 6d. the usual price before the present excessive rise, £2 14s. leaving a profit of £1 13s. 9d. As by another mode of reckoning, rent or interest = one bushel, ploughing and harrowing = one and a half bushels, harvest = one, seed = one, taxes, and all other small articles, = half a bushel; together, five bushels; leaving a profit of seven, which at 4s. 6d. amount to £1 11s. 6d. This has been looked upon as sufficient profit, when it was considered that maize. not wheat, is the most profitable crop of the farm, according to the common opinion of the country.

But I think it would be easy to prove, and it is so held by those who have paid most attention to the subject, that maize is every where a losing crop, and has been destructive to America; but it is not to our purpose here to inquire into the fact; should, however, this opinion not be well founded, the £1 11s. 6d. above stated as profit, certainly is not net; because the wheat and the maize must pay for their neglected waste, and also for the worn out old-field, which produces little or nothing.

Should this deduction be allowed, little profit can be found in the present mode of agriculture of this country, and I apprehend it to be a fact, that it affords *a bare subsistence*.

The quality of the wheat of this state, is the only thing that remains to be considered.

The wheat of New York is esteemed the best of any in the United States, and that grown on the banks and branches of the river Mohawk, the best in the state.

I had opportunities of examining considerable quantities of it, at Albany, in October, 1794, and found it in general of a very good quality, clean, and well dressed: the best sample that I could meet with (and which probably was as good as any that could have been produced,) weighed, by the bushel that was said to accord pretty accurately with that of *Winchester*, which is the only measure of grain known upon this continent, 64¼ lbs.: this, I was informed, was the utmost weight of wheat produced in any part of America.

The standard weight is 60 lbs. for all extra weight in all purchases, the grower is paid an additional price; and he deducts in proportion for all that falls short of it. It is good wheat that weighs 58 or 59 lbs.

JERSEY, PENNSYLVANIA, DELAWARE, AND MARYLAND,

Have so many circumstances in common, that they may, in this instance, be taken together: except Pennsylvania, none have any *backlands*, and these have only been settled since the peace, are yet not much known, and little produce has yet come to market from them. These four states much resemble each other in the nature of their climate, and quality of their soil, and, from a long continued course of bad cultivation, are much in the same exhausted state; the crops heretofore have been in the following rotation. First year, maize; second, wheat; third, *rubbish pasture.* By this frequent recurrence of the same crops, the land had become so far exhausted, as not to produce, upon an average, more than six bushels per acre of wheat; and much land still continues in the same course of cultivation; but an alteration has of late pretty generally taken place, in which one of the following rotations will be met with; first year, maize; second, wheat; third and fourth, rubbish pasture: or first, maize; second, fallow; third, wheat; fourth, rubbish pasture; but the fallow is stated to be so very imperfect, as to be little better than the rubbish pasture; or in the same year with wheat, frequently buckwheat standing for seed will be met with: either of these rotations will produce eight bushels of wheat. Clover is in some places just beginning to be introduced, and is said to increase the produce of wheat at least five bushels to the acre, in some such course as the following: first, wheat; second, maize; third, wheat; fourth and fifth, clover: or first, wheat and buckwheat; second, clover; third, maize; fourth, wheat; fifth and sixth, clover, or other variations of these crops.

In the peninsula of Maryland and Delaware, which produces the best wheat in this district, the old rotation of maize, wheat, rubbish pasture, is still continued, and the average produce of it is thought not to exceed six bushels per acre: in some instances, not more than two bushels are produced, and much is so bad as to be ploughed up again.

Not more than three pecks of wheat are sown for *corn-land wheat;* that is, wheat sown after maize, here emphatically called *corn.* From this lamentable state of ignorant cultivation, must be excepted the tract in Pennsylvania, inhabited by the Germans.

This industrious people, fortunate in possessing one of the finest parts of America, the country at the eastern foot of the mountains in Pennsylvania, have, either from superior knowledge when they arrived in the country, or superior attention to the nature of the soil and the climate, brought the cultivation of their country to a degree of excellence, which may vie with that of many of the old countries of Europe: their wheat may be averaged at eighteen bushels per acre; twenty-five bushels are frequent, and instances of thirty are not wanting; sufficient proof of what the country is capable of producing, were the culture of it well attended to. Their barns, their buildings, their meadows and pastures, are all in a style of neatness and perfection, unknown in other parts of America; by the use of gypsum they have clover, and by irrigation, meadows superior, particularly the former, to any I ever saw elsewhere, either in America or England: to them ought certainly to be given the credit of introducing irrigation into this part of America, and, I believe, the knowledge of gypsum into every part of it.

The tract, however, which they occupy, comparatively with the four states now under view, is of so small an extent, that I cannot estimate the average produce of the whole of these four states, at more than eight bushels per acre; the abundant crops of the Germans will not counterbalance the six bushel crops, and those of even less, of so many extensive parts of them. The profit arising from eight bushels, particularly as applicable to Maryland, has been thus calculated: rent or interest of capital, one bushel and a half; once ploughing and harrowing, one bushel; seed, one bushel; taxes, which are next to nothing, and all other little expenses, half a bushel; total four bushels, leaving a profit of four; straw is reckoned to pay all expenses of harvesting and thrashing, which it could not do, were it not in Maryland particularly valuable, for hay is there scarce, and all cattle are maintained in winter on straw and grain; but these four bushels cannot be fairly stated as profit; where in a three or four year's rotation, fallow and rubbish pastures intervene, their expenses must be paid for by the maize and wheat. The wheat grown in this district, particularly in Maryland, though not the heaviest, is thought to make the best flour of any in the United States; the best will weigh 63 lbs. and there, as in New York, 60 lbs. are held to be the average, according to which purchases are made.

[To be continued.]

REPORT OF THE PRESIDENT AND DIRECTORS OF THE RICHMOND AND FREDERICKSBURG RAIL ROAD.

The board, at its first meeting, appointed Moncure Robinson, Esq., the chief engineer of the company, with instructions to organize his party of assistants, and have the location of the rail road commenced as early as practicable. Both in the location and construction of the road, he was informed, that the board desired to proceed as vigorously as practicable, having due regard to economy and stability of execution. Acting under these general instructions, Mr. Robinson proceeded to organize a party of assistants and to execute during the past summer and fall, minute and extensive surveys, preliminary to the selection of any part of the route. The result of these surveys, has been the location of a line of railway between Richmond and the Mattapony, superior in every respect even to the sanguine anticipations of the board, and the execution of which, will, it is ascertained, be effected at a considerable reduction from the first estimate of the engineer.

The examinations which the engineer is now making between the Mattapony and Fredericksburg, will, it is believed, result in improvements in this part of the line, equally important. Should this belief prove well founded, it is confidently anticipated that the whole expense of the work to Fredericksburg, including the cost of depots, warehouses and water-stations, locomotive engines, cars and carriages, will not exceed an aggregate sum of 650,000 instead of $763,182 21 cents, the first estimate.

At a meeting of the board on the 2nd of October, the engineer was authorised to put under contract in December following, such portion of the line as might then be in readiness. The portion then in readiness embraced 27 miles between Richmond and the North-Anna, and was put under contract by the engineer on the 27th of December, agreeably to previous notice. The work was undertaken generally by highly industrious and responsible contractors, at reasonable prices, and has so far been prosecuted by them with great energy. In consequence, however, of the unfavorable winter and spring, as much progress has not been made towards the completion of their contracts, as it was expected would have been made by this time, and it is feared that the same cause may prevent in some cases a reasonable profit being realized by the contractors. Latterly the work has been prosecuted under more favorable circumstances than existed in the winter and spring, and the anticipation of the board, that this first division of the road would be completed by the close of the present year or very early in the next, they feel confident will now be realized.

The president was authorized at the first meeting of the board, to make purchases of real estate in the City of Richmond for a depot. Under the authority given him, he has purchased lots No. 477, 478, and parts of lots No. 496 and 789; lot No. 477, being at the corner of H and Eighth streets, lot No. 496, next above it, lot No. 478 in its rear, and lot No. 789 next below. By the act incorporating the company, it was requisite that the point at which the rail road was to terminate within the corporation should be approved by the common council. It appearing to the board most expedient, to conduct the rail road from the Richmond Turnpike along H street to a point at or near the intersection of the said street and Eighth street, and for the present to terminate the same by suitable connections with the contemplated warehouses and workshops of the company on the lots before mentioned, a resolution was adopted on the 22nd of December, 1834, requesting the approbation of the common council to this plan, and on the 23rd of that month the common council approved the proposed location of the road and present termination of the same, and authorized the prosecution of the work within the limits of the city on the said location. The warehouses and workshops have since been put under contract and are now in progress, and no doubt is entertained that they will be ready for use at as early period as will be necessary to meet the construction of the first division of the road before mentioned.

Arrangements have been made for placing on this portion of the road immediately on its completion the requisite engines and cars for the accommodation of the trade and travel. So soon also as this portion shall be ready for use, Messrs. Edwin Porter & Co. have agreed to connect with it their lines of stages and steamboat transportation to and from Washington City, and to deliver and receive passengers and their baggage on and from the cars of the company. As the accomplishment of this portion of the road will reduce the distance to Fredericksburg, now 67 miles, to 59 miles, and the time of travelling it more than one-third, it is obvious that the whole travel through Virginia on the northern and southern mail route must pass upon the rail road as soon as this first division of it shall be in readiness for use.

In view of this result the board confidently anticipate being enabled to declare a dividend to the stockholders in little more than twelve months from the present time, and before much more than fifty per cent of the stock shall have been paid in.

At an early meeting of the board Dr. Joseph M. Sheppard one of their body, was requested to make proper arrangements with the owners of such lands on the route as were required for the purpose of the company, and in those cases in which no agreement could be made with the owners, to take proper measures to have lands condemned and damages assessed according to law. The board are pleased at being enabled to state to the stockholders that the benefits of the improvem nt to the country through which it passes, appear to have been generally appreciated by the land owners. In most cases, releases of damages have been freely given, and in others where it has been necessary to apply to the courts for the appointment of freeholders to assess damages, their awards, except in a few instances, have been fair and reasonable.

A different view of the subject, by the owners of lands, or by commissioners, would scarcely have been anticipated. Forming as this rail way does a link in the great line of communication between the north and south, and executed on a route so cheap and favorable, there is every reason to believe that in a very short period the maximum dividend allowed by the charter may be expected from the northern and southern travel. When that period shall arrive, it would seem to be the clear policy of the company to charge on the transportation of produce and merchandize tolls very little, if at all, higher than may be necessary to pay the expenses of transportation, and to look for the profits of stockholders, to the travel chiefly, perhaps entirely.

The act incorporating the company, authorized subscriptions to be received to the amount of $700,000, of which three-fifths would have been $420,000. The subscriptions actually received during the ten days that the books were originally kept open, amounted to $305,200; being $114,800 less than three-fifths. One of the first questions before the board was as to the expediency of re-opening the books of subscriptions. Satisfied as the board was of the future productiveness of the stock, they entertained no doubt that if the books were re-opened for the purpose, there would be a prompt subscription on the part of individuals of the balance requisite to make up the three-fifths, but they resolved in the first instance to offer to the corporation of Richmond, the option of subscribing for this balance, or for any portion thereof. The common council declined acting upon the subject. After they so declined, the board allowed the books to be re-opened on the 19th of November, 1834; and subscriptions were received on that day, to the amount of $44,600. On the same day a memorial to the general assembly was adopted, asking a subscription by the commonwealth when three-fifths of the capital stock should have been subscribed by individuals. While this subject was before the general assembly, the board had reason to believe that the deficiency in the subscription of three-fifths by individuals, though small, might yet be urged as an objection to the usual subscription in such cases by the state, and on the first of January, 1835, the books were re-opened and additional subscriptions received to the amount of $75,000; making the whole sum subscribed by individuals $424,800, or 4,800 more than three-fifths. After this, an act was passed authorizing the board of public works to subscribe on behalf of the commonwealth, and requiring that board to make the subscription, when it shall appear that at least one-fourth of the private subscriptions of not less than three fifths of the capital stock have been actually paid up, and when certain other conditions are complied with. All these conditions will be immediately complied with, and the board of public works, it is presumed, will thereon make the subscription. When this subscription shall have been made, the whole capital stock will be subscribed that is at present allowed by the charter of the company.

In their applications both to the common council of Richmond and to the legislature of Virginia, the opinion of the board was expressed as to the future productiveness of the stock. The gradual rise in its price from par to seven dollars and ten cents per share above par, furnishes strong evidence that, in the judgement of the community, that opinion is well founded. The board now venture to express their belief that within a very short period after the completion of the work ample evidence will exist of its value in adding to the trade of the city and developing the resources of the state.

A branch rail road which has been projected from the neighborhood of Taylorsville to the South West Mountain, for which it is understood a charter will be asked at the next session of the legislature, must add largely to both the trade and travel of the road, and may be expected to stimulate the industry of the region through which it will pass, by conveying its products more cheaply and quickly to market. A rail way to connect the Richmond and Fredericksburg Rail Road with that between Petersburg and the Roanoke, will, it is believed, be equally an object of legislative attention. The execution of these two works must promote greatly the public interest and convenience, and at the same time add largely to the productiveness of that committed to the undersigned.

With such motives to impel the rapid completion of the enterprize, the board have made all their arrangements to effect the work between Richmond and Fredericksburg at the earliest practicable period. The location having proceeded beyond the North-Anna, a resolution was adopted on the 16th of May, 1835, authorizing the engineer to put under contract from time to time, further portions of the line. And it is now confidently believed that the whole line between Richmond and Fredericksburg will be in readiness for the transportation of passengers, merchandize and produce, in eighteen months from the present time.

The following persons were unanimously re-elected president and directors, to continue in office until the next annual meeting, to wit:

JOHN A. LANCASTER, President,

NICHOLAS MILLS,
CONWAY ROBINSON,
JAMES BOSHER,
RICHARD B. HAXALL and
JOSEPH M. SHEPPARD, } Directors.

WM. P. SHEPPARD, Secretary,
R. F. & P. R. R. C.

THE SHEEP DOG TAKEN.

Riga, *May* 9, 1835.

Sometime last fall a strange dog commenced depredations among the sheep in Avon, destroying some nights between 20 and 40. He soon became the terror of the town, and various measures were resorted to by individuals to destroy him, but without effect. To such an extent were his depredations carried, that at last the people turned out *en masse*, and drove him from the town; but not, however, until he had killed between three and four hundred sheep—merely sucking the blood and seldom feasting upon the carcasses.

He was next heard of in the vicinity of Pine Hill, Genesee county, last winter, where rising of one hundred sheep became his victims. From that place, as at Avon, the people, before getting rid of him, were obliged to make a general turn out. The dog was driven into Bergen, and in that town and this, (Riga) he has within the last two or three months, destroyed over 300 sheep and lambs, having been alternately driven from one town to the other.

Although the dog has been hunted by various individuals, (the army often amounted to hundreds) since he took up his unwelcome residence in the town last named, and notwithstanding some of the best marksmen in these towns, as well as those where he has pursued his work of death for six months past, have made frequent shots at him, he has never to my knowledge, asked for quarters, nor was he finally conquered until this evening.—It was yesterday determined to make a general assault upon this common enemy, and take him if possible; and a reward of about $80 having been previously offered, by a subscription for his scalp, about two hundred persons belonging to this town and to Bergen, headed by General, Major, Colonel, Captains, and other necessary officers, took up their line of march to-day for the south part of this town, where he had last been seen, and about noon routed and drove him into what is called Adams' Swamp, which was immediately surrounded; dogs were sent in to drive him out, and about six o'clock he emerged from the woods, and in crossing the road leading from Mr. Adams' to Buel's corners, was shot through the heart by Roswell Parish, Jr. of this town, a lad aged about 17 years.

By the blowing of horns and firing of guns, the company was soon congregated—the fallen foe was placed in a wagon—the company were formed into a double file, at the head of which as a mark of honor, was placed the fortunate young marksman. The procession then marched to Riga corners, where the dog was hung up by the neck and a general salute fired—after which they proceeded to Bergen corners, where they took the skin from the dog and stuffed it.

PETRIFIED BUFFALO.

This extraordinary curiosity was discovered about two years since by some trappers belonging to Captain Bent's Company, lying on the side of one of the beaver dams of Rio Grande of the north (a stream emptying itself into the Gulf of California) whose waters, it is said possess the petrifying qualities to an eminent degree; its shores abounding in specimens of various animal and vegetable productions in a petrified state. The petrified Buffalo is described by those who have seen it, to be as perfect in its petrifaction as when living, with the exception of a hole in one of the sides, about four inches in diameter, around which the hair has been worn off, probably by the friction of the water, in which it must have lain for ages past to have produced such a phenomenon. The hair on the hump, and shoulders, neck, forehead and tail, though concentrated into almost a smooth surface, may be easily discerned. The horns, eyes, nostrils, mouth and legs, are as perfect in their stone as in their pristine state.

The country in which this rare specimen was found, is inhabited by the Euteaux, a roving tribe of savages, who subsist, a great portion of their lives, on insects, snakes, toads, roots, &c. This tribe being particularly hostile to the whites, renders the acquisition of this curiosity an undertaking not a little hazardous. Notwithstanding this, and many other difficulties to be surmounted, such as distance, expense, &c. our enterprizing citizen, Captain Charles Bent, contemplates procuring and bringing the specimen to the United States with him on his return from Santa Fe, during the ensuing autumn. We heartily wish him success in his praiseworthy undertaking.

From the Leesburg (Loudoun) Genius, June 13.

THE HARVEST.

The time is near at hand when our farmers are wont to cut their harvest. Sad and gloomy is the prospect, not only in this county, but as far as we have heard, with very few exceptions, throughout the wide and diversified country. There are some farmers in Loudoun, who, owing to the localities of their farms, will make nearly an average crop; but they are few. By far the greatest part will not reap more than their seed, with perhaps a sufficiency for domestic use and enough to defray the expenses of harvesting. Others will not make their seed. This is certainly very discouraging, and must have a tendency to enhance the price of wheat and flour very considerably.

From the New York Star.

AMERICAN CHAMPAGNE—TRENTON HEIDSIECK.

We have been informed by a gentleman who is thoroughly conversant with the subject, that the universally favorite and fashionable wine champagne, is manufactured or rather counterfeited at Trenton, New Jersey, to an incredible extent. A large establishment has been built, warehouse, laboratories, &c. for three or four hundred boys and girls, making wicker baskets, and an immense number of bottles, branded corks, such as "anchor," "hard," "comet," "Joly," &c.—and also, expert alchemists in compounding these articles, imported for the express purpose from the vineyards of *la belle France*. Well, if these precious drinks are from the incentive of high prices to be counterfeited, we know no more exquisite domestic nectar than our famed Newark cider, which, with all the honey in our market, have, we learn, been bought up for the Trenton factory. Such a composition must be infinitely superior to the mock champagne manufactured in France, which is impregnated often with the deleterious admixture of sugar of lead. The Trenton Heidsieck, with its leaden caps and false bottomed bottles complete, bring, we hear, a ready sale at $7 the dozen, in baskets. A gourmand, an epicure we should say, was most beautifully bamboozled the other day with this cheap champagne, and boasted at a dinner party what an admirable bargain he had made.

CULTIVATION OF MUSHROOMS.

Whoever has been accustomed to eat mushrooms, will certainly allow them to be one of the greatest dainties the earth affords, especially the *morel*, *truffle*, and *champignon*. The morels chiefly appear in April, and the truffle about that time may be dug out of the ground; for they never appear above the earth. Those who make it their business, in foreign countries, to gather the truffles, have only one way to find out where they grow, and that is by the help of a hog, which they lead in a string through the woods, suffering him to root the earth as he goes along; for swine being very voracious of them, discover them by their smell, and turn them out of the ground. These kinds have never, I believe, been cultivated, although they are sometimes found upon our plains and commons. The champignons may be raised in gardens in the following manner. Dig a trench six inches deep, lay in it the dung of horses, mules, or asses, then cover the dung about an inch thick with fresh earth, such as is just taken from under the turf, rather sandy than otherwise, and then cover the whole bed with straw or dry litter, as well to defend it from frost in winter, as from the scorching heat of summer's sun. The bed being thus prepared, water it twice or three times a week, without taking off the covering of straw, and in about a month's time the mushrooms will begin to appear. These beds must be made every month to produce mushrooms all the year. The late famous Mr. Harrison, of Henly, made mushroom beds much after the same manner, only instead of horse dung, he made use of old thatch, which turned musty and grew mouldy much sooner than horse dung, and would produce mushrooms quicker, and in greater plenty. Half rotted straw, moistened with lime water, will also produce mushrooms in great abundance. The cuttings of white poplar, steeped in hot water, well fermented with yeast, will produce very good mushrooms in a few days; and the loose chips of the same tree, being buried in a decayed hot bed, will do the like.

To make mushroom catsup.

Break them into an earthen pan, strew salt over, and stir them now and then for three days. Then let them stand for twelve, till there is a thich scum over; strain, and boil with Jamaica and black peppers, mace, ginger, a clove or two, and some mustard seed. When cold bottle it, and tie a bladder over the cork—in three months boil again with new spice, and it will keep two years.

To dry and powder mushrooms.

Lay them on tins or seives in a slow oven till they are dry enough to beat to powder: then put the powder in small bottles, corked, and tied closely, and kept in a dry place. A tea spoonful will give a very fine flavor to soup or gravy, or any sauce. It is to be added before serving, and one boil given after it is put in.

To stew mushrooms.

Sprinkle with salt and pepper—simmer slowly till done; then put a small bit of butter and flour, and a little cream: give them one boil and serve with sippets of bread.

VEGETABLE INOCULATION. KNOWN AND PRACTISED 120 YEARS AGO.

The following experiment of Mr. Lawrence, was made 120 years ago, which he mentions in his "Clergyman's Recreation," relating to the jessamine.

"Suppose a plain jessamine tree spreading itself into two or three branches from one common stem near the root. Into any one of these, in August, inoculate a bud taken from the yellow striped jessamine, where it is to abide all winter, and in the summer when the tree begins to make its shoots, you will find here and there some leaves tinged with yellow, even on the other branches not inoculated, till by degrees, in succeeding years, the whole tree, even the very wood of all the tender branches, will be most beautifully striped and dyed with yellow and green intermixed." He adds, that "though the inoculated bud should not shoot out, or that it should live but two or three months, and after that, happens to die or be wounded by accident, yet even in that little time it will have communicated its virtue to the whole sap, and the tree will become entirely striped."

SUBSTITUTE FOR COFFEE.

A German physician, by the name of Mark, discovered that acorns may be used with advantage as a substitute for coffee. Considering the high price of this article, it will prove a discovery of much importance.

S.

For the Farmers' Register.

SUBSTITUTE FOR TEA.

The wood of the tender branches of the sassafras, dried in the shade early in the month of May, makes an excellent substitute for foreign tea. The bark has a stronger taste and smell than the wood; and from the quantity of volatile oil it contains, is too stimulating and heating. The tree is cultivated in Jamaica, and the inhabitants commonly employ the root in making tea.

S.

For the Farmers' Register.

QUICKENING GERMINATION.

"M. Humboldt has made several experiments on the subject of the germination of seeds in the oxymuriatic acid diluted with water, and has found that this acid has a remarkable effect in accelerating the progress of vegetation. Cress seed, when thrown into the fluid at the temperature of 88, showed germs in three hours, while none were seen in water in 26 hours. Professor Pohl, at Dresden, produced, in this manner, vegetation from dried seeds 100 years old; and Messrs. Jacquin and Vander Schott, at Vienna, have caused the growth of old seeds in the botanical garden which had resisted every other method."

ON THE BREEDING, REARING, AND FATTENING OF SHEEP.

[Continued from p. 167 Vol. III.]

On the Merino, or Spanish Sheep.

The sheep of this foreign species have horns of a middle size, of which the ewes are sometimes destitute; faces white; legs of the same color, and rather long; shape not very perfect, having a piece of loose skin depending from the neck; bone fine; pelt fine and clear.*

The wool of the Merino sheep is uncommonly fine, and weighs upon an average, about three pounds and a half per fleece. The best Merino fleeces have a dark brown tinge on their surface, almost amounting to black, which is formed by dust adhering to the greasy, yolky properties of its pile; and there is a surprising contrast between it and the rich, white color within, as well as the rosy hue of the skin, which peculiarly denotes high proof. The Merinos are natives of the northern provinces of Spain, and were first introduced into this country in the year 1787; but it was not until 1792 that any effectual measures were adopted towards improving our native breeds by a Spanish cross. In the last-mentioned year his majesty George III. received several rams of the Negretti breed; but so great was the force of prejudice, that notwithstanding the manufacturers confessed the wool of the Anglo-Spanish cross to be of prime quality, yet not one individual bid for it a price at all equal to what they paid for good Spanish wool. From these sheep imported by his Majesty, and from the great exertions of the late Lord Somerville, (who at an immense expense imported a flock of choice Merinos,) great benefit has been derived to the wool, by crossing this sort with the best British breeds, although the produce of the cross has not been improved in shape. The most successful cross has been with the herfordshire, the fleece of which is heavier, in proportion to the carcass, than that of any other known breed in Europe, the average weight of the fleeces of two-shear ewes being estimated at four pounds and a half avoirdupoise, in an unwashed state; and the fleece of a fat wether of the same age will be from five to seven pounds.

From the high prices which Anglo-Merino wool commanded during the late war, great expectations were formed of the advantages to be obtained from the introduction of Spanish sheep, which were accordingly imported to a great extent, and sold at very high prices†. Of some of the crosses with that breed, we have already seen the result: its effect has also been tried in Sussex, upon the south-down sheep, by Lord Sheffield, and other eminent breeders, and the wool of the flocks was thereby considerably improved; but it was accompanied by some capital defects, not to be compensated by any improvement of the fleece—tender constitution, slow feeding, bad shape and deficiency in the number of lambs. This new breed has therefore been generally given up in Sussex,* and also in Wiltshire, where it had been extensively tried.† There are still, however, many large flocks of pure Merinos, the proprietors of which affirm that their qualites are not only uninjured, but have even been improved by their naturalization in this country. So far as regards the carcass, this may be true; but some of the evidence before the late committee of the House of Lords goes to prove, that the wool has become more harsh; a statement, it may be observed, which is corroborated by the difficulty in selling it, and rendered probable by the difference of climate and of treatment to which the animal has been exposed;‡ though at the same time it is admitted, that the weight of the fleece has been increased, and that the price is double that of south-down.§ The flesh is also fine; but, notwithstanding the improvement of the carcass, the return in mutton is still deficient.¶

In Spain, the sheep from which these flocks have been obtained, are bred in the northern provinces of the kingdom of Leon, and of Segovia and Soria, in Old Castile, and the district of Buitrago, in New Castile; from whence, after being shorn, they are driven southward at the approach of winter, and remain dispersed over the plains of Estremadura, La Mancha, and Andalusia, until the return of summer, when they travel back to their native pastures; and whether from instinct or habit, they are said to display symptoms of restlessness as the time approaches for their change of pasture. They are, in consequence termed *Trashumante* flocks—those which are stationary being called *Estántes;* and there is a code of regulations, sanctioned by the authority of law, for the government of the shepherds during these periodical migrations. The ancient pasturages in the south are secured to them at a fixed rate. A strip of land, of considerable width, is left in pasture at each side of the road for their accommodation, without which they could not travel with conve-

¶ Evidence of Mr. Webb Hall, of Sneed Park, Gloucestershire, ditto, ditto.

nience; and the greatest attention is paid to secure these privileges. By thus removing them at the different seasons from north to south, and back again, they are kept in a nearly equal temperature and it probably is to that advantage that the superiority of the wool of the Trashumante flocks is to be attributed; that from those which remain stationary, being far inferior; as a proof of which, the *Caçeres*, or Estremaduran wool, grown in one of the central provinces, commands little more than half the price of the *Leonesa*. It must, however, be admitted that, in Spain, it is a disputed point whether the travelling flocks are really benefited by the equality of climate thus obtained; some stationary flocks in the province of Segovia being said to produce as fine wool as any of the Trashumante.

If the supposition that the change of pasture be correct, it must follow that these sheep, when exposed to the variable climate of this country, will necessarily change the quality of their fleece; upon which, climate is known to have the greatest influence. It may, indeed, be said, that the change might even then be advantageous; for a certain degree of cold is rather favorable than otherwise to the growth of fine wool; and its improvement in Saxony, into which country the Spanish breeds were introduced about half a century ago, might be adduced as an instance in point. But in Germany, these sheep are regularly housed during the winter; they are also kept, during that season, on dry fodder, which may be supposed to have a material effect on the fleece, for the Spanish sheep are kept on bare, and generally burnt up, pasture, without ever tasting artificial fiood; and our finest woolled flocks are maintained on the scanty herbage of the downs.

In France—where the royal flock of Rambouillet, picked from the best in Spain, was introduced in 1785*—the sheep suffered greatly by the cold until housed; and although the Merino breed has been since naturalized in that country, and still retains the fineness of the texture of the wool, yet it looses in softness and in strength of staple.

The Trashumante flocks have existed from a very early period in Spain. There is an ancient tradition that the original stock was obtained from this country; but it has not been traced to any authentic source.* In the sixteenth century they were calculated at seven millions; but their numbers have since much diminished, and they are now supposed not to exceed five.

The chief flocks are those of *Paular*, which belong to a richly endowed monastery of that name in Segovia;—of *Negretti*, the property of the Marquess of Campo d'Alange;—of the *Escurial*, formerly belonging to the crown; and those owned by the Duke de l'Infantado, the Marquesses d'Iranda and Péralès, and Count San Rafael; each of which consists of from 40,000 to 60,000, and the average weight of the fleece is estimated at 5lbs.†

The total export of Spain formerly amounted to about 32,000 bags, of 250 lbs. each; but this is daily diminishing, in consequence of the rapid increase of the German fine wools, and of the great depreciation of prices in this country. But little is consumed in the manufactures of Spain, especially since the revolution, which put a stop to the great royal manufactory of Guadalaxara. An attempt was, indeed, recently made to re-establish those magnificent works, through the medium of a public company formed in London; but, like most of such projects, it failed. It is, however, not improbable that the present extremely low prices of wool, in Spain, will induce the Spaniards to manufacture for themselves: if not, the Trashumante flocks will decrease, for the fleece being the sole object of that system, it will be no longer worth pursuing; if the wool should continue, as at present, a mere drug in their markets; and it has, besides, been long considered as prejudicial to the real interests of the kingdom, by its retaining immense tracts of land in the southern provinces in comparatively unprofitable pasture.

*By a treaty made between France and Spain, during the French Revolution, 5000 ewes and 500 rams, of the best Spanish breeds, were placed at the disposal of the French Government.

* See, on this subject, Pennant's British Zoology.

† Bourgoing: *Tableau de l,Espagne Moderne, Vol. I. Ch. III.* This estimate is, however, higher than the usual average.

SYNOPSIS OF THE DIFFERENT BREEDS OF SHEEP IN GREAT BRITAIN.

				Average weight of wool, per fleece.	Average weight of wethers per quarter	Years old when killed.
				lbs.	lbs.	
Heath,	large horns,	black faces and legs,	coarse long wool,	3½	14	4½

On the Breeding and Management of Sheep.

Before we proceed to discuss this branch of rural economy, it will be necessary to state the names or terms by which these animals are generally known at different ages; though even these vary in different counties.

From the time of weaning to the first shearing, the males are denominated *hogs, hoggets*, or *hoggerels*, after which they receive the appellation of *shearing, shearling, shearhog*, or *diamond tups*, or rams; after they are called two, three, or four shear, according to the number of times they have been shorn.

When male sheep have been castrated, they are termed, from the period of weaning to that of shearing, *wether* or *wedder hogs*, then *shearings, shearlings*, &c.; or they are afterwards denominated *two-tooth*, then *three*, or *four-tooth wethers*, and finally, *full-mouthed*.

The females have the appellations respectively following:—from the time of weaning to the first shearing they are termed *ewe* or *gimmer hogs;* they then take the name of *gimmers* or *theaves*, which continues only for one year, after which they are invariably denominated *two, three*, or *four shear ewes;* and, when old, they are termed *crones*.

Sheep, in general, renew their first two teeth from fourteen to sixteen months old, and afterwards every year, about the same time, until they are turned three years old, or rather *three shear*, to speak technically, when they become full-mouthed; for, though they have eight teeth in the under jaw before, it is believed they only cast or renew the six inside ones. But, with regard to this point, there is a difference of opinion among experienced shepherds, some of whom conceive that they cast only six, while others think they renew the whole eight fore-teeth.

With respect to the selection of sheep, as an article of *live stock*, the same principal of symmetry of form, and other requisites to the formation of a good breed of black cattle, which have been already specified, are equally applicable. The breeder, or grazier, should also carefully examine the nature of his land; and having attentively weighed its relative degrees of fertility, and his various sources for supplying food, he may then proceed to purchase that breed, which, after mature consideration, he has reason to believe is best calculated for him. In this point, the introductory view of breeds and varieties, already referred to, will probably afford some guide; but there are some additional hints, to which we would call his attention. In the first place, therefore, he should take care not to suffer himself to be led into needless expense, in purchasing fashionable breeds, by which his affairs might become involved, and his exertions in other objects be rendered nugatory; though he should be scrupulously attentive to procure the best blood of that particular breed on which he may fix. Secondly, the difference of the land, whence the sheep are to be purchased, ought to be attentively weighed; for with sheep, as with cattle stock, if any breed be brought from a rich to an inferior soil, it must necessarily decrease in value and condition. Not only, therefore, must sheep be suited to the pasture, but they should also be purchased, if possible, from poorer land than that of the intended proprietor, for on attention to this last point depends their immediate thriving.

Having thus noticed the general objects in selecting sheep, we now proceed to state some particular points that will demand the breeder's attention; and, as in all cattle the male has the greatest influence, we shall specify those requisites which are essential to a good ram.

"His head should be fine and small; his nostrils wide and expanded; his eyes prominent, and rather bold and daring; ears thin; his collar full from his breast and shoulders, but tapering gradually all the way to where the neck and head join, which should be very fine and graceful, being pefectly free from any coarse leather hanging down; the shoulders broad and full, which must at the same time join so easy to the collar forward, and chine backward, as to leave not the least hollow in either place; the mutton upon his arm, or fore-thigh, must come quite to the knee; his legs upright, with a clean, fine bone, being equally clear from superfluous skin, and coarse hairy wool, from the knee and hough downwards; the breast broad and well forward, which will keep his fore-legs at a proper wideness; his girth, or chest, full and deep, and, instead of a hollow behind the shoulders, that part, by some called the fore-flank, should be quite full, the back and loins broad, flat, and straight, from which the ribs must rise with a fine circular arch; his belly straight; the quarters long and full, with the mutton quite down to the hough, which should neither stand in nor out; his twist (i. e. the junction of the inside of the thighs) deep, wide, and full, which, with the broad breast, will keep his four legs open and upright; the whole body covered with a thin pelt; and that with fine, bright, soft wool."*

Such is the description of the animal recommended by Mr. Culley, who observes, that the nearer any breed of sheep comes up to it, the nearer they approach towards excellence of form; and there is little doubt, but if the same attention and pains were taken to improve any particular kind, which have been bestowed on the Dishley breed, the same beneficial consequence would be obtained. It should, however, be remembered, that symmetry consists in that shape which is best suited to the soil on which the animal is to be bred; and thus that which may be thought perfect in a Leicester sheep may be found inferior in a South Down or a Cheviot.

In addition to the symmetry and other requisites above specified, the *pelt*, or coat, should also be attentively investigated, lest it be *stitchy haired*, in which case the wool will be so materially damaged, in the course of two years, that the injury cannot be remedied for a long period, unless the whole flock be changed. But the fineness of wool is not the only criterion by which it should be judged even in the short wooled breeds: the *staple* is also of the greatest importance; though on that material point—on which the substance and wear of the cloth so much depends—it may, however, be observed that the, now fashionable, Saxon wool is far inferior to the fine Spanish growths of Leonesa and Segovia.

Ewes generally breed at the age of fifteen or eighteen months, though many experienced breeders never admit the ram till they are two years

---

* Culley on Live Stock, pp. 103, 104.

old. Much, however, depends, in this respect, on the goodness of the food, as well as on the forward or backward state of the breed. The choice of ewes, therefore, ought to be made with care and discrimination, not only as to the characteristic marks, which ought to be the same as those of the ram, but also with regard to the breed; for, with sheep, as with other cattle stock, no certain degree of excellence can be attained, unless the female possesses an equal degree of blood with the male. In particular, a purchaser should see that the animals be sound; and, in order to ascertain this point, it will be advisable to examine whether the teeth are white, the gums red, the breath not fetid, the eyes lively, the wool firm, and the feet cool; qualities these which afford a certain criterion of health or disease.

Of equal importance is the proper selection of rams, even of the same breed and apparent qualifications: in attending to which point, the conduct of the Duke of Bedford (whose memory every real friend to his country must revere) deserves to be imitated by all attentive breeders. Previously to drawing off the ewes for tupping, it was his constant practice to select every ram, together with the lambs begotten by it in the preceding year, from the rest of the flock, and confine them in separate pens, in order that he might examine them and their issue, by the value of which he was guided in his determination.

Ewes bring forth one, two, and sometimes three lambs,* after a gestation of five months, or twenty weeks; hence the sheep farmer, or breeder, may, in general, by considering whether he has sufficient grass to support the ewes and their progeny in the spring, ascertain the most advantageous period for lambing; or in the event of a failure of pasturage, whether he has a stock of turnips adequate to their maintenance till there is a sufficient herbage to supply them with food.

The usual time of yeaning is towards the end of March, or early in April; consequently, the rams are, according to the general practice, admitted in the commencement of October. But in the county of Dorset, where the ewes are, from a peculiarity in their constitution, capable of bringing lambs at a much earlier period;* and also in the southern and south-western districts, where large quantities of house-lamb are raised for the table, it is most profitable to deviate from this plan, and so to admit the ram, that the lambs shall be dropped from four to six weeks, or more, earlier.

The strength and beauty of sheep stock also greatly depend on the number of rams allowed to serve the females. While the former are young, fifty or sixty should be the utmost extent; and, as they advance in years, the number may be gradually increased; without these precautions, the lambs would not only be deficient in number, but also in point of strength.

Various expedients have been resorted to, in order to make the ewes *blossom;* among others, is the practice of worrying them with small dogs, kept for that purpose, in consequence of which they become warmed, so that they seldom refuse the ram. In Leicestershire, a practice was introduced, at Dishley, of employing *teasers;* that is, inferior rams with a cloth so fited on them, as to prevent copulation; and whose duty it is to prepare the ewes for the visits of the sultan of the fold. But it is much better, and certainly a more rational plan, to keep the rams and ewes in different pastures, till the time when they are intended to be brought to the rut: and for about five or six weeks before, let them have somewhat better pasture than they are usually accustomed to, by which expedient they will be disposed to take the ram the sooner. In fact, it is with sheep as with other cattle, the female must be in a certain state desirous of the male before the latter will attempt to serve her; and this object can only be artificially attained by increasing the richness of their food a short time before they are required to couple; for, in proportion to the excellence or poverty of their food, the bodily vigor of these animals must evidently increase or diminish.

During the period of gestation, ewes require great attention, lest any accident should occasion them to slip their lambs; and, if that should take place, it will be proper to separate them instantly from the rest of the flock. Where they are not pastured upon open downs, or moorland, the best plan is to keep them in the same manner as cows, while going with calf, namely, upon a moderate, or tolerably good pasture, where no object can disturb them; and it is also advisable to give them turnips, or similar green food, under the like precautions, till within the last two or three weeks before their yeaning. In the breeding of cattle, indeed, it is a maxim which ought to be steadily kept in mind, that nothing can be more prejudicial to the females than to fatten them during gestation; and with respect to ewes in particular, this rule should be more carefully observed than with regard to any other animal; for if they be fed too high while they are going with lamb, they will undergo great difficulty and pain in yeaning: whereas, unless they are put into a little heat before that period arrives, they will not only be deficient in strength at the critical moment, but also be destitute of a sufficient supply of milk for the support of the lamb, and consequently both the dam and her progeny must be greatly weakened, if

---

*The most prolific sort is the *Tees Water* variety of the Lincolnshire breed, of which Mr. Culley has given the following instances. An ewe belonging to a Mr. Eddison, when two years old,

In 1772,	brought him four lambs,
In 1773,	five lambs,
In 1774,	two lambs,
In 1775,	five lambs,
In 1776,	two lambs,
In 1777,	two lambs;

and of these the first *nine* lambs were yeaned in *eleven* months. But such instances are of very rare occurrence, and deserve notice rather as being curious deviations from the usual course of nature, than as affording any real ground for calculation.

According to Mr. Teissier's experiments on gestation, (already alluded to in the previous books,) out of 912 ewes,

140	lambed between the 146th and 150th day; mean term	148
676	150th and 154th day;	152
96	154th and 161st day;	157

The extreme interval being 15 days to a mean duration of 152.

*It is commonly, but erroneously supposed that the Dorset ewes bring forth lambs twice a year; such instances have occurred, but they are rare.

they do not actually perish from such mismanagement.

As the time of yeaning approaches, the attention and assiduity of the shepherd ought proportionably to increase, as it sometimes becomes necessary to assist nature in cases of difficult parturition; and also, if in the open air, to drive away crows and similar birds of prey, which might otherwise assault the newly dropped lambs, and pick out their eyes, notwithstanding all the efforts of the dam.

As soon, therefore, as the ewes are expected to begin to yean, they ought to be separated from the rest of the flock, and placed in a more sheltered paddock, or in a spacious standing littered fold, on one side of which should be a warm cottage hut, provided with a chimney, and with a stove for warming milk, and also with a bed on which the shepherd may lie down. Here he is to sleep during the lambing season, that he may be ready to watch, assist, and tend any ewes which he observes to be very near lambing, and, if necessary, to give aid to the young animal. Some farmers have such huts on four wheels, to draw about with the flock wherever they may be, and on extensive downs that is an excellent plan; but on farms of a moderate size, it is a far preferable method to have one or two well-sheltered inclosures, to which the flock may be taken without any distant driving: for, although the fold may be useful in very exposed situations and inclement seasons, yet the practice of folding ewes at lambing time is generally objectionable.

It has already been intimated, that turnips are of great service in giving a flush of milk to ewes, unless they have been weakened by difficult parturition, in which case it is considered rather prejudical than otherwise; and, as many drop their lambs at a very early period in the year, great care is necessary in supplying them with these useful roots, so as to insure a sufficient quantity. If the land be wet and liable to be poached, the best mode is to draw the turnips, and cart them to a dry pasture, where the sheep may be baited with them once or twice in the day; proper attention being bestowed that they eat the whole, without committing any waste; which, if duly observed, will afford a certain criterion of the quantity necessary for each bait, while the stock of roots will be consumed in the most benefical and economical manner. On dry lands, indeed, a different practice may, with advantage, be adopted, by eating the crop on the land, hurdling off a certain quantity for the flock; and, as they consume these, by extending the hurdles further. By this method, no considerable degree of trouble is occasioned; and, it is preferable to that of allowing the sheep to run over the whole field, by which the roots are never eaten off so clean as when the flock is confined to a small quantity at one time.

During very wet or stormy weather, or in deep snows, it will be necessary to bait the ewes on hay. With some farmers it is usual to drive them to hay-stacks, where they meet both with shelter and with food; a measure which is by no means consistent with the economy that ought to exist in every department of farming business, in the manner in which it is commonly practised, but which might be rendered in all respects expedient, by merely fencing the stack round with hurdles, and distributing the hay from it daily. When placed in the centre of a standing fold, a square stack forms an excellent defence for a small flock, against bleak winds, as they have quite sufficient sagacity to seek its leeward side. By others, again, the hay is given in moveable racks, and a stated portion *per day* is allowed. This is an excellent method while on turnips, let the weather be good or bad, for it corrects the watery quality of the food; and sheep thus fed are found to thrive better than upon either hay or turnips alone. In some parts of the kingdom, the most experienced farmers give their ewes and lambs bran and oats, or oil-cake, in troughs, while they are feeding on turnips; but the expense attendant on this practice can only be repaid by a superior breed.

By the course of feeding here detailed, the sheep may be successfully supported till the month of March, about which time the stock of turnips upon the land is generally consumed; so that every attention should be paid to have a proper supply of spring food. Among the many expedients resorted to for this purpose, may be mentioned the turning of sheep into a spot of rye sown for the purpose, or into crops of wheat, in order to feed them off; a practice which, however, is necessarily confined to arable farms, and can seldom be carried to a sufficent extent. Other resources are the letting the animals run over the clover and pasture of the farm; hence the crops of hay, and pastures for large cattle, receive material injury. Others have an adequate spot of land, under ray grass and clover, ready to take the ewes and lambs from turnips, before they are turned in upon the pastures. The last mentioned practice is undoubtedly the best; but it may be materially assisted by removing *Swedish turnips* from the ground and stacking them upon layers of straw, after having cut off the tops and roots: the common turnip will become sticky; but Swedes, treated in this manner, will retain their nutritive quality until towards summer, and will be found essentially serviceable at this trying season. *Turnip, cabbages*, the *ruta baga, green borecole*, and especially *burnet;* all afford singularly useful crops for spring feed. The latter has the peculiar property of maintaining its verdure throughout the winter: so that, even under deep snows, some luxuriance of vegetation may be discovered. In November, it should be four or five inches high: and, by February, the crop will gain two or three inches in growth in the young leaves, when it will be ready for sheep.

Infinitely preferable, however, to any of these useful articles of late spring feed for ewes and lambs, is *rowen*, or the aftergrass, kept on dry meadows and pastures after the hay-harvest is concluded. Although a field of rowen presents an unpromising aspect at a distance, in color not unlike very bad hay, yet when this covering is removed, a fine green herbage, from five to six inches in height, will appear; the whole of which is eaten with avidity by the ewes and their young progeny, who are thus supported till they are turned into the pasture, and being a sure resource, while others may fail, should never be neglected.*

---

*Mr. Young gives it as his opinion, that rowen is the cheapest mode of keeping a full stock in April. If of a tolerable quality, he estimates that it will carry ten ewes on an acre, *together* with their lambs, through the whole of April; and computes its relative value to be, With regard to the best time for *weaning* lambs, much depends upon the period, or season, when they were yeaned. When a lamb is to be kept for breed in a good common pasture, it is the practice in some counties to wean it at the end of about four months, in order that it may become strong, and that the ewe may acquire strength and go quickly to blossom. In others, which are more mountainous and poor, the lambs are weaned a month earlier. But whatever influence local customs may have in this respect, this business should be performed before the expiration of July; and, as it is of essential importance to their future growth, and consequently to the breeder's profit, that due provision be previously made, it will be proper to remove the lambs to a distance from the ewes, to such fresh food as may be most convenient. Clover, while in blossom, is the most forcing food; sainfoin rowen may also be successfully employed for the same purpose; but nothing is superior to a sweet bite of fresh pasture-grass. On weaning the young animals, their dams may be milked two or three times, in order to relieve their udders, which would otherwise become painful.

When lambs have been once stinted in their growth, either by disease or insufficient food, they become what is technically termed *sticky;* after which, although they may be in apparent health, it is out of the power of art to fatten them. It is, therefore, of the utmost importance both that the ewes should have abundant food, in order to produce a flow of nutritious milk while they are suckling; and also that the lambs should have plenty of good pasture, or of other succulent green meat when they are weaned.

Various ages are mentioned as being most proper for *gelding* those lambs which are not intended to be raised as rams for breeding; but the sooner this operation is performed, the better it is for the animal, which is more able to support it while young, and running with the dam, and when there is less danger to be apprehended from inflammation. The time best calculated for this purpose, in the opinion of the most experienced farmers and breeders, is within the first fortnight, unless the lambs are unusually weak, in which case it will be advisable to defer castration for two or three weeks, or such longer term as may be expedient, till they acquire sufficient strength.

In grazing farms, in general, it is not only of great importance to dispose, at certain times, of such beasts as either become unprofitable, or are sufficiently fat for sale, but also to separate the stock and place them in different pastures, according to their age and condition. In the southern counties of this island, the severing of sheep usually takes place about six, eight, or ten weeks after the shearing is finished, or in the course of the middle of August. In making this selection great care should be taken to choose those only which give indications of their being of the true breed (whatever that may be;) and, according to their comparative strength or weakness, to regulate their pastures. Hence it will be proper to place those animals which are designed for breeding or fattening by themselves: the ewes by themselves; the *wedder* or *wether hogs,* (i. e. males, whether castrated or not, that are of one year's growth,) and *theaves*, or females, that are two years old, by themselves; and the old wethers and rams by themselves; and lastly, the lambs by themselves; otherwise the stronger animals will injure such as are weak, and prevent them from taking that food which would be most beneficial for them.

When a farm is thus stocked with a proper assortment of sheep, it will be necessary for the owner to inspect them often, particularly in the winter; and, either to remove into better feed, or to dispose of those which do not thrive upon their allotted grounds; but, independently of these examinations, the shepherd ought constantly to continue with his charge, as they are liable to various maladies, which, if not speedily attended to, will carry them off in a very short time.

Before we close the present discussion respecting the management of sheep, it may not be improper to advert to one or two practices materially connected with them. The first is that of *docking*, or cutting their tails; which prevails not only in this country, but likewise in Spain, Saxony, and, generally speaking, in every district where the inhabitants pay much regard to the improvement of wool-bearing animals. The tails are usually cut when the lambs are three or four months old; for, if the operation were deferred beyond that time, it could not be performed with safety to the animal. This practice is objected to by some intelligent breeders in England, on the ground that it renders sheep unable to defend themselves against the attacks of flies during hot seasons: by others, however, it is strongly recommended, because it tends to preserve the health of the animals, by keeping them more clean from the odor which they, in a great measure, deposite on the fleece, and gives the animal a square, handsome appearance on the hind quarter. It is very generally adopted, except by some breeders in exposed situations, who, not unjustly, conceive that the long bushy tail affords considerable protection and warmth to the udder of the ewes in very severe weather.

The other practice above alluded to is, that of *extirpating the horns of sheep;* which has hitherto, we believe, been confined to the sheep-walks of Spain, and to the sheep-farm at Rambouillet, in France. The reasons assigned for it, and the manner in which this operation is performed, are detailed by M. Lasteyrie,* but we deem it unnecessary to insert them, as the practice is not likely to be adopted in this country.

In fine throughout the whole system of sheep husbandry, the greatest attention is necessary, on the part of the *shepherd,* regularly and frequently to inspect the animals committed to his charge. From the nature of his employment, which is usually exercised at a distance from his master's eye, he is under but little control; the property in his care is generally valuable, and always requires the closest attention; the greatest circumspection is therefore necessary in choosing an experienced and trustworthy person for the office; but when such an one is found, his services should not be grudgingly remunerated. In Saxony the shepherds have not fixed wages, but are allowed a pro-

---

in autumn 10s. or 12s.: in spring from 30s. to 40s. per acre; and, if the season be backward, that a farmer who possesses it would not be induced to dispose of it for a more considerable sum.

---

* Histoire de l'Introduction des laines fines, &c. p. 236.

fit on the produce of the flock. From the adoption of this arrangement, the sheep-masters derive great advantage, as the shepherds have no inducement to deceive them, and are themselves interested in taking due care of the animals committed to their charge. This practice has also been adopted by some large flock-masters in Scotland with great success: how far it may be feasible in England it would be rash in us to assert; but as the hint seems worthy of attention and trial, we leave it to the consideration of the intelligent reader.

The *Shepherd's Dog* performs so important a part in the management of sheep, that some notice of his qualities cannot be deemed irrelevant to the subject. The species which is delineated in this work occurs chiefly in the extensive sheep-walks in the northern parts of this island, where the purity of its breed appears to be preserved in the greatest perfection. Its docility and sagacity, indeed, surpass those of every other variety of the canine race: obedient to the voice, looks, and gestures of his master, he quickly perceives his commands, and instantly executes them. A well-trained dog of this kind is, to a shepherd, an invaluable acquisition. The faithful animal anxiously watches the flock, keeps them together in the pasture, from one part of which it conducts them to another; and, if the sheep are driven to any distance, he will infallibly confine them within the road, and, at the same time, prevent any strange sheep from mingling with them.

In Prussia, there is a peculiar breed of dogs employed in the management of sheep: it is described by M. Lasteyrie as being of a small size, but stout and thick, with erect ears, and bearing some resemblance to our wolf-dogs: their coats are partly smooth and lose, while others are long and shaggy. They are remarkably docile; *never bite the sheep;* and at their masters' voice, repair instantly to that part of the flock which is pointed out: in case the sheep hang behind, *these dogs push them forward with their muzzles;* which is sufficient to make the sheep take the requisite direction. An importation of a few of this breed would certainly be worth the trial: or if the Prussian mode of teaching our dogs not to bite, could be acquired, it would be a most desirable object. The continual state of fear in which those naturally timid animals are kept by a dog that has not been properly trained, disturbs their repose, and prevents them from feeding quietly; and, in fact, it rarely happens in any flock, that there are not some sheep which are from time to time lacerated, more or less severely, by the bite of dogs.

From the Genesee Farmer.

ROTATION OF CROPS.

I have ever considered the notion which has been advanced in some of the English agricultural journals, that the matter thrown off in the soil by a species of plants is poisonous to other plants of the same kind, if grown in succession, as most unphilosophical, and contrary to fact. Some of the advocates of a doctrine of an absolute necessity in all cases for a rotation of crops, found in this supposition of excrementitious poison, a very convenient argument for their system, and hence it has obtained some currency both at home and in this country. Farmers, however, of all men, should be the last to be wedded to theory, as theirs is a profession eminently practical. It is too late in the day to "doubt" that the system of rotation in crops, under proper circumstances, is of the first importance in agriculture. Its effect, however, does not depend on the extinction of excrementitious poison, but by a renewal of the proper food of plants. That the influence of rotation has been overrated by some English and American theorists will not be disputed, and when the time comes to underrate, of which some symptoms can be discerned already, it is at least probable it will be as injudiciously decried. That corn will grow in succession for half a century on the Genesee flats—wheat for thirty years on some of the favored wheat lands of West New York—and oats for twenty years on some of the slaty soils of Cattaraugus, without much diminution of quantity, I can readily believe; but exceptions like these to the system of rotation only demonstrate the propriety of the course in general. To us it appears the doctrine of rotation is founded on very simple principles, capable of easy and successful application, and hardly leaving room for doubt or disputation. That plants during their growth do take up, and appropriate as nourishment, very different materials from the same soil, will not be questioned by any one who has paid the least attention to vegetable physiology. For instance, does the pine apple or the orange take as much silex from the earth as the bamboo or the rattan, some of the species of which have an outer covering so hard as to strike fire when struck together?—or, to select a more familiar example, does the Faden contain as much of the salt called potash as the elm or beech?—and how does it happen that while 1000 pounds of wormwood yields 784 lbs. of saline matter, the box and the aspen produce but 70? This faculty of taking up particular substances as food, and the necessity of the supply, holds good in the cereal grasses, such as wheat, rye, barley; in corn and oats; in roots, such as potatoes, carrots, turnips, beets, &c. They all find and assimilate as nourishment different ingredients from the same soil, or appropriate them in very different proportions. If the soil of my farm abounds in those aliments essential to the production of wheat, I can raise crop after crop from the same land, and rotation is needless; and this course of successive crops will be successful in exact ratio to the continued supply of proper food. If, however, the proper food of the wheat plant is limited, a rotation of crops, and manuring, by which this quality can be restored, is indispensible. It is so with corn, oats, and most other plants. The rich alluvion of the Genesee flats is apparently inexhaustible by corn; perhaps 90 parts in 100 are suited to the growth of that important article; but this fact does not prove that other and less favored soils cannot be exhausted, or will not be benefited by a rotation. I have seen some of the oat lands spoken of by Mr. Allen in a former number of the Farmer, and feel a pleasure in bearing testimony to the general correctness of his views, and justness of his remarks; yet the facts he has stated furnish perhaps one of the strongest arguments in proof that different plants take up different materials from the same soil, and therefore that rotation must, in most cases, be advantageous. Those lands in the southern tier of counties of which Mr. Allen has spoken, as producing such abundant crops of grass and oats, are, it is well known, worthless for wheat, the flour of the little they do produce being of a very inferior quality, and no more resembling that of the counties bordering on the lakes, than does the rye flour of the eastern states. I should put but little confidence in the theoretical notions of any man, who could imagine that the farming of a whole country can be made to conform to a single system, or pattern. There is an almost infinite variety in the original ingredients of our soils and their proportions, and the mode of treatment, to be judicious, should be as near as possible made to conform to these variations. There are some general principles every where applicable, and there are others which have but few exceptions; of the latter class I consider to be the doctrine of the utility of rotation in crops. My friends, the practical as well as theoretical Ulmus, or the "doubting" R. M. W., may be so fortunate as to possess farms which will admit of an unbroken succession of wheat crops, but I imagine the farmers of Old Onondaga will in general agree with me, that the simple rotation of wheat and clover has more enhanced the productiveness of their farms, and consequently rendered them more profitable and valuable, than would successive but necessarily diminished crops of that valuable grain, and important staple of our country.

W. G.

From the Farmer and Gardener.

RIBBON GRASS.

I wish to make a few remarks on some experiments that I am making, though now in their infancy, on a species of grass here named and known as the ribbon grass. This early disclosure of results, as far as they have gone, is rendered the more necessary, inasmuch as I have recently seen an extract from a letter of mine in an agricultural paper which though not intended for the public eye, found its way to the press. To this course I have not the slightest objection; but on the contrary, will feel especially happy at all times, if what I may say should be of service to my countrymen, of letting whatever I may write be published. The circumstance to which I allude was this. I mentioned in a letter to a friend, that I had seen a patch of ribbon grass, in a very flourishing state on a wet, boggy spot of ground, and of my full belief of its being susceptible of being very extensively and profitably cultivated, and of my intention of trying the experiment. As this has been communicated to the public, and as I have had a very favorable account of it from a gentleman in Connecticut, an experienced and practical farmer, and of his determination of entering into its culture immediately, I deem it proper that I should make known my own experiments and opinion of this grass, believing as I do that it will prove a most valuable acquisition to the cultivated grasses, and a great blessing to the people of the south in particular.

A neighbor of mine, (Capt. John Simpson, living in Greenland,) knowing I had made some experiments on grasses, observed to me that he had a patch of ribbon grass on a springy, boggy piece of ground, which it was worth my while to see. It was his belief, from its luxuriant growth in the *bog*, and the circumstance of its expelling all other grasses, taking full possession of the soil, and affording two full crops in the season, and from the fact *that all kinds of stock were very fond of it, that it might be cultivated to great advantage.* This excited my curiosity, and I soon called on the gentleman to satisfy it, and was surprised at the beauty and richness of the grass. It grew on a bog at a small distance from a living spring, where the water descended and spread through the grass all the season. The appearance of the neighboring grass in the same situation, was very ordinary, being thin, flat-leafed, short, and nearly worthless—whereas the ribbon grass, in every particular, wore the most beautiful appearance of any grass I had ever beheld. It was then in its vigor, and in full bloom, every leaf being expanded, wide and thick, so that the eye could not penetrate through it. Each leaf has one or more stripes lengthwise, differing, on close scrutiny, from each other, either in the number of stripes, or their form or shade. This grass averaged about four feet in height, and stood perfectly erect. It is possessed of a fine solid stock, having an inviting and luscious appearance as fodder. I took a clean lock of it, and another of herds grass, and offered them both together to my horse, and found him quite as fond of the ribbon as of the herds grass.* Capt. Simpson states that he has observed that his stock were more fond of it than of his best hay of other kinds. This patch would amount to about one square rod.

I engaged the seed, not knowing what it produced, having never particularly observed the grass before; I accordingly applied at the proper time as was supposed, and reaped the heads, but was able to discover but very few seeds, from one to three to the head. Being certain that we were full early, a part was suffered to remain till later in the season—when by a re-examination it was found in the same condition. I beat and rubbed out the chaff; but could discover only a few small seeds. I sowed it in good season, with the greatest care, in my garden, hoping that in the chaff, there was more than what I could discover, which would vegetate. I sowed it in drills, to be sure to have it well covered, and that I should not mistake other grasses for it. There appeared to come up a few white blades, which I supposed to be young ribbon grass; these few, however, dwindled off one by one, till all disappeared, the ground never having been disturbed since, and I have not one plant to show from these seeds. Hence I conclude it *cannot be propagated from the seed.*

Having a very favorable opinion of the grass, I looked for some way to propagate it, and concluding that it might be multiplied from the *root*, as hops and many vegetables are, I accordingly engaged one-half of the patch, to take it in the spring. I prepared my ground (40 rods) by ploughing in my low ground in the fall, the ground varying from soft to very soft mud. The spring being wet, the ground uncommonly soft and muddy, I postponed the setting of it out, I think, till June, when I went for my wagon load of turf, the grass

---

* Mr. Robinson means timothy, that being the name by which it is designated to the eastward.—Ed. Far. and Gard.

was then from four to eight inches long. Early in the spring it had had a dead appearance, but at this time it had become pretty well sprung up; some old stubs were dead. Perhaps this situation was one of the most trying of any to be found. It grew where ice made to a great thickness from the water spraying from the spring all the year. Mr. Simpson has informed me since I took away one-half of his turf of the ribbon grass, that it sprung immediately up in the same place, and produced a crop quite as good as before. Since his closer observations, he says he esteems the grass more highly than at first.

The manner in which this grass was planted in the bog, was this. He had a tuft of it growing for ornament in his garden, in a very rich soil; which he occasionally ploughed, and finding the ribbon grass spread a little too far, he ploughed off some of the roots, gathered them and threw them into the bog; he found they took root, spread and flourished as I have stated. I observed when getting my grass, there were some low spots covered with water, where the grass sprung up stronger and larger, being apparently more in its element.—Capt. Simpson's garden is of the richest soil among us; yet it is evident that one rod of the bog will produce as much as four in his garden. Immediately after getting home with my turf, I commenced chopping it up, taking care to divide the tufts according to the stalks, leaving from one to three in each piece, choppig them with a sharp spade, into pieces, from one to four inches square, setting out about 40 square rods, about two feet apart, without any manure; and setting a few for experiments in the middle furrow where the water was constantly issuing nearly all the season. None of them failed of living, and all have taken root, shot out and spread considerably; some few to meet each other. Those in a dead furrow appear every way as thrifty as those on the bed. I had the curiosity to try the experiment by sticking one stock of this grass without root in the mud, where the water continued to issue: it appeared to grow as well as those with the root; and shot out with branches. This method of propagation is more facile than from the root. I pressed several tufts into holes in a bog where the water would rise to the top of the tufs, (this is among fresh grass,) here it shot out and appears in its element, and will in all probability spread and drive away all the other grasses. I also sunk some into what is called a quagmire, where it is so soft as not to bear a cat; here I sunk the tufs level with the water; these have the appearance of being perfectly in their element. All these I have lately surveyed since our severe cold, and those in the wettest places appear least effected. I set some of them out on some of the most barren soil, under a forest of white oaks, where nothing of consequence will grow: they all live there, and will probably produce something, perhaps one ton to the acre; if it will do this on very barren lands, it may be well to cover them over with it. I have set it in my front yard and in my garden, on warm soil of tolerable quality, bordering on common grass, in part for ornament. A portion of this was manured and hoed; here it is perceivable that the higher the culture the greater the product as it respects high ground. It is demonstrated from my experiments, and Capt. Simpson's discovery, that this grass is truly amphibious. It will do well on high dry lands, and it will thrive in a bog or even in water. I do not know how deep a water it will grow in, but I presume it will grow in shoal, especially running water. Is it not evident that this grass possesses very valuable properties, and must prove superior to most other grasses?—Yes, for it not only grows luxuriantly and in abundance in a quagmire where nothing of any value has ever been known to be produced before, but its roots are of such a tough nature, that a sward is soon produced that will bear a cart and oxen to pass over it. It has another good quality:—although the circumstance of this grass not producing seed for propagation, seems at first view to lessen its value—yet when we consider the evils resulting from many troublesome grasses that spread from seed, and that no limits can beset them; we may, with propriety, esteem it a virtue in this fast-rooted grass, that limits, can be set to it, that our valuable tillage ground may never be impeded with its roots, and that our waste and unproductive bogs may be easily changed to the most productive portions of our farms. As to what *Ribbon Grass* will do in pasture, I know nothing. I have my doubts whether it will succeed, as I think it is not thick and downy enough, to bear repeated trampling and cropping close to the ground. It is possible, however, from its hardiness, wherever it has been known by me, that it may endure the hardship of being pastured; if so, I have a right to conclude from all its other properties, that it will prove far more valuable than any species of grass yet introduced into culture (the gama not being fully known,) and if any farmers at the North or South, have waste bogs that are eye-sores within their enclosures, let them try the experiment of the culture of this grass: it will not be costly, even if they should not succeed.

ABEDNEGO ROBINSON,

Of Portsmouth, N. H.

From N. Y. Jour. of Com.

MOWING MACHINE.

We have seen at the shop of Mr. Johnson, in Cherry Street, a mowing machine, which we are told is the first of the kind built in this country. The cutting operation is performed by circular knives fastened upon the periphery of a horizontal wheel five feet in diameter. This wheel is suspended upon a perpendicular iron shaft, which hangs upon a lever, by which the knives are raised or lowered at the pleasure of the driver to suit any unevenness in the ground. The motion is given by geering, connected with the wheels, on which the whole machine rests. The machine will weigh a ton, and is moved by two horses. Upon the horizontal wheel, and just within the edge of the knives a tub of light wood, which has the effect of carrying the mown grass into a swath. We see not but that the thing will work well on smooth land, but where there are rocks of much unevenness it cannot. It is said to be capable of mowing ten acres a day, and certainly, for the mower, it is much easier to ride on this machine, than to swing a common scythe. The machine was invented in England, but the laborers there, probably under the guide of some philanthropic leader, made war upon it, and would never permit it to be used in peace.

IMPROVEMENTS BY MARLING IN NORTH CAROLINA.

To the Editor of the Farmers' Register.

Newbern, June 22, 1835.

DEAR SIR—I have lately received from Mr. Benners the enclosed letter, and supposing it to possess some interest for you, I have accordingly forwarded it. I should be pleased to send you some of Mr. Benners' specimens, if an opportunity of forwarding them should be found. Mr. B's position, you may remember, is on the northern bank of the Neuse River, about 16 miles below Newbern. He is the only person in this section of country who has any considerable experience in marling. A few other persons however have begun to make experiments.

Yours respectfully,

H. B. CROOM.

P. S. The marl pits of Mr. Benners are remarkably interesting for the variety of shells and fossil bones which they afford. These have proved, in the estimation of Mr. Conrad, the existence here of the *newer pliocene* formation.—See *Silliman's Journal* for April, 1835.

TO H. B. CROOM, ESQ.

Roseville, June 14, 1835.

Dear Sir—In reading the Essay on Calcareous Manures, I learn for the first time, that our shell marl is *not* what is properly understood by marl in English books and practice. The solution of the two kinds is widely different. The test of marl is pure water—and acids the test *we* use for the same purpose. Observing this fact, I immediately recognised an old acquaintance overlooked and neglected by me, as I only *knew* him by the name of *clay*, but since his introduction to my notice under his *proper name*, I have made it my business to become more intimate with his character and *calling*, and find upon investigation, that marl is his *real name*. Brick mortar has certainly done him great injustice, both here and in England, in assuming the garb, quality, and character of marl —to the great loss and detriment of society in general, and farmers in particular. At the same time begging pardon for our past neglect of him, and promising every attention to him in future, we remain his humble servant. About ten years past, I did offer this marl a glass of vinegar, but having refused it, I cut and broke off all farther acquaintance, until latterly, I have fortunately discovered he is a pure water drinker. It is also remarked, that he is none the worse for his temperate habits. Nos. 1 and 2 are samples of this marl. I am now enabled to give you an account of the position and order of the different kinds of marl as they come to view in working the pits.

The first bed is a fat blue or red clay marl. Nos. 1 and 2, from two to five feet below the surface, and from three to seventeen feet thick.

The second bed under this, rich red or yellow shell marl, from one to five or six feet thick—effervesces in acids.

The third bed is a very *deep blue* marl, without shells, with here and there the impression of the whole exterior surface of the shell, forming a cell in which is a lump of marl the size and shape of the *fish*. This kind is very tough to cut up, but when dry, crumbles to a very fine powder, as light as ashes, and about the same color—effervesces in acids. Specimens No. 3.

The fourth bed is (either) a blue or white shell marl, and works like coarse mortar, hardens in lumps as it dries, but crumbles in moving about—effervesces in acids. This last or lower bed is from three to five feet below common tide-water, and has never been worked through. I have selected from the different beds of shell marl, a variety of specimens which I intend sending to you very shortly, and some fossil bones, &c. I am at present working a pit which exhibits the different strata, in the order in which I have attempted to describe them above, but very imperfectly.

It is very easy to be deceived in the strength of marl by merely handling it, or by the eye, as I have experienced the injurious effects of a too liberal application of it on an impoverished soil. Fifteen years ago, I *burned up* a piece of an old field by laying on too great a quantity of shell marl at the first dressing: but it is now excellent land. As this was my first experiment, (1818) I was mortified and disappointed, and was of course laughed at and ridiculed, because the experiment had fulfilled the prediction of those who merely guessed at what they knew nothing about. I soon discovered my mistake by observing that where the heaps were left unspread, and ploughed through and planted, that the young corn died, and that no grass would grow on the pure marl—but this was not the case in the intervals between the heaps; these spaces showed evident improvement, but so very gradual, as to be unobserved by every one but myself, and the hands employed on the farm. I soon perceived that my land was getting better. My means were extremely limited, and of course my land improved in proportion, and continues so to do up to the present moment. I very soon discovered that manure went a great deal farther on my marled land, than on land of a better quality not marled. The improvement, however, became at length too evident to all to be any longer doubted; but the *jest* continued, and the whole improvement placed to the credit of the manure, of which I have never raised as much as would afford a tolerable dressing to half of my corn crop, without the marl, and both combined with enclosing and alternate cropping; corn, cotton, potatoes, and wheat or rye: * the land divided in two equal parts, and one-half tended as above described, while the other half remains enclosed. This is the course I have pursued steadily for the last fifteen years, and have no disposition to change it for a better, unless our climate was more congenial to the cultivation of artificial grasses. White clover grows in my fields, but receives no assistance from cultivation—it dies in July and August, while the crop grass and carrot weed cover the land, and are invaluable, being capable of resisting the dryest and hottest weather.

*Rye should succeed corn and potatoes on all our light lands, instead of wheat. It is a most profitable grain for stock, and the quality and texture of our high lands are admirably adapted to the production of this grain, as a very profitable crop. My attempts at a good crop of rye have never failed—wheat on the other hand is just as uncertain.—L. B.

Whether land is sour or sweet, I am not chemist enough to determine: but I *do know* that the red sorrel will *not* grow on marled lands, as I have had a very fair opportunity of being abundantly satisfied. The whole of my land was covered formerly *knee deep* with a most luxuriant growth of this beautiful plant. At this time there is none to be seen, nor for the last eight or ten years.

With great respect,
I remain, dear sir,
Your obedient servant,
L. BENNERS.

[We learn from the foregoing letter what we had no idea of before, that Mr. Benners' experience of the use of marl commenced as long ago as 1818—the same year of our own first effort to profit by this mode of improvement. That the benefit of marling should have been so long exhibited, in a region eminently fitted to reap its richest rewards, without inducing others to follow the example, and *scarcely* to believe in the results, are facts both strange and lamentable. Nothing can place in a stronger point of view, the former and existing want of intercourse and exchange of opinions among farmers, and of the vast importance of agricultural periodical publications, as a means of remedy.

Mr. Benners seems to have placed an erroneous construction on a part of the work which he refers to, and which it would be improper here to pass without notice. In stating and proving at length that English farmers and writers have very often called *marl* what was merely *clay*, but slightly if at all calcareous, the author did not mean to contend for the correctness of the application of the term—but directly the reverse: and he would neither attach the name of marl, or consider of much value as manure, any *clay* which was not calcareous.]

LOW PRICED AGRICULTURAL PUBLICATIONS. EXTENSION OF THE PLAN OF THE FARMERS' REGISTER.

Low priced newspapers, and other periodical publications, are now so common, and so little regard is paid by the majority of readers to the considerations which ought to recommend more costly works, that some concession must be made to the prevailing opinions, in this respect, to be enabled to spread any publication very widely. Especially does this apply to agricultural publications among the middle class of farmers, by far the most numerous and important class, both as farmers and as citizens, and therefore the most desirable to attract and retain as readers and subscribers. Unless the main ingredient of a publication consists of party politics—the exciting and maddening intellectual food of thousands to whom every other kind is insipid, or repulsive—scarcely any periodical at $5 a year can now obtain very general circulation in the southern and western states.

It is unnecessary to state here, the various causes of expense which serve to add to the price of a periodical published in the manner, and form of the Farmers' Register—or to show, as might easily be done, that for its cost to the publisher, its style of execution, and for the amount and value of its contents, that it is truly a cheap work. This is so well understood by the greater number of those who are its present supporters, that they would not choose to have its form changed, and to yield the peculiar advantages of its present plan, for any consequent abatement of price. Neither is it our wish or intention, to lessen the value or the beauty and convenient form of the present publication—but on the contrary, to continue (as has been commenced already) to give increased cost and value to the material, and mechanical execution, and to as great extent as the object requires, and the means may authorise. But while carefully guarding against impairing the value, or lowering the grade of the Farmers' Register, as now published, it is highly desirable to suit the wishes, and gain the support, of the very many farmers of Virginia, and adjoining states, who have not yet learned the value of agricultural periodicals, and who will not profit by them, except when conforming to their general and commendable (though in this respect mistaken) views of economy. However extensively and liberally this journal has been supported, it must be confessed that it has comparatively made but little progress among the middle class of proprietors. It is true, that some farmers whose poverty forbids their indulging in any useless expense, and who labor daily and assiduously for their maintenance, are among our subscribers—and we are proud to have their support, because the amount of expense to them, is equivalent to a very high estimate of the value of the work. But for every one such, whom we can boast of as a subscriber, there are perhaps fifty who are rich, or at least in the possession of competent fortunes, who have withheld their aid, and that on account of the expense of the subscription. Without stopping to oppose the soundness of this objection, it will be admitted that it exists, and operates extensively—and every friend of this journal, and to the cause which it is designed to support, will admit the high importance of removing this obstacle to its circulation, and of gaining access, if possible, to a far more extensive body of readers.

With this view, a low priced publication is proposed, consisting of a single sheet, to issue four times a month, and to contain nearly the same matter as the monthly publication. But getting rid of the cost of the difference in the value of paper and of execution, and of the entire cost of various other matters peculiar to book work, and to the mode of delivery of our present publication, the work in the cheaper form may be furnished at little more than half the present price, and yet yield as much profit upon the same amount of annual receipts. Or in other words, 3000 subscribers at the rate of $2.50 would yield nearly as much profit, as 1500 at $5. The vast difference of benefit to the general interests of agriculture, which will be caused by the greater number of subscribers, is a sufficient inducement for us to risk the possible contingency of loss from a smaller accession of names, and of course a proportional diminution, in future, of the present amount of receipts. A specimen sheet and proposals will be issued, and the publication commenced as soon as there appears sufficient indications that a publication on this plan will be approved and sustained by the agricultural community: and if it is well sustained, there shall be nothing spared or omitted to make the diffusion of agricultural knowledge through the southern states both as extensive and *as cheap* as possible.

CROPS IN BEDFORD. AGRICULTURAL PAPERS.

To the Editor of the Farmers' Register.

Lynchburg, June 19*th*, 1835.

* * * * I have just returned from the country, (my farm in Bedford, 22 miles above this) where I find a small portion of the wheat crop tolerable good, but the mass very inferior—and a large part of that on the corn ground not worth cutting, even if it escapes the rust. This failure is ascribed in some degree to the unfavorable winter, but mainly to the ravages of the Hessian fly. Many of our planters have wholly, or partially discontinued the culture of tobacco; and by attention to manure, clover, and plaster, and better ploughing, have improved their lands to a considerable extent: but the prospects of the wheat crop, connected with the present price of tobacco, will, I apprehend, produce much backsliding, and many of us be found again to have "returned to wallowing in the mire;" so that this seeming good—the high price of tobacco—may be to us a real evil. The rye, oats, and corn crops appear rather promising, and the frequent rains of late, have enabled the planters to pitch their crops of tobacco without difficulty.

In a late number of the Register, you remark that your subscription is confined chiefly to the low lands. Your locality, your level and sandy lands, your marl beds, your easy access to lime, and other circumstances, produce a greater difference between our situation and yours, than with the same elevation would exist in several degrees of latitude. From these circumstances, I had no idea of taking the Register until I read your Essay on Calcareous Manures; and I have no doubt many are deterred from even looking into it from the same causes. The price too being higher than many other publications, may have some effect. Sixty odd numbers of the Cultivator, and several of the American Farmer, and Genesee Farmer, are received at this post office. I state this, not by way of complaining, but in explanation: for it is my opinion, that every sensible farmer, whatever may be his latitude or longitude, elevation or depression, may read your Register and your Essay with manifest advantage. With my best wishes for the continued success of your useful endeavors, I am, &c.

MICAJAH DAVIS, JR.

[The foregoing letter (post marked June 24,) was not received until after the last No. was printed, or it would have appeared earlier.

It is gratifying to learn that however small may be the patronage of the Farmers' Register in Campbell, other agricultural papers are more welcome there. The subscribers who receive the Farmers' Register at Lynchburg are only twelve—and there have never been more, nor so many until recently. If the price of this journal is the *only* bar to its receiving more favor in the upper country, a proposal has been made for its removal, by a similar publication of low price. But if there are objections to the general character of the work, or to the manner in which it is conducted, they will still remain in full force. Let farmers generally be but impressed with the importance of reading and sustaining agricultural periodicals, and we are content that their support shall be given to the most deserving, even if our work should be surpassed by many others in merit, or in other claims to public favor and support. If the great object is effected, it is of but little importance (and none whatever to the public,) by what means, or by whose agency, the end is reached, and the benefit produced.]

CORRECTION—"VIN MUET," OR DUMB WINE.

To the Editor of the Farmers' Register.

Columbia, S. C. June 10, 1835.

I have read with pleasure your article on "the making of wine in the canton of Mareillac." I take the liberty of observing to you that one word "mutage," [p. 23, Vol. III.] seems not to have been understood by your translator, and there is nothing surprising in this; for the technical expressions of particular arts are not easily understood, and they are not found in dictionaries. It is to be hoped that the new dictionary that is announced as coming forth, after many years' labor by the French Academy, will contain this and all such terms, without which it will not be complete. The verb "muter," signifies "to render mute," or dumb, which is done to wine by sulphuring it. *Mutage*, therefore means sulphuring. There is in some places a wine made that is called "Vin Muet," literally "dumb wine." It is wine that has been fumigated to excess with sulphur, before fermentation has taken place, which chemical process is thereby prevented, and the wine remains sweet. It is called "mute" because the bubblings of the fermentation are not heard, and it actually makes no noise. This word then is not near as bad as most others which no etymology can clear up.

N. HERBEMONT.

[We thank our correspondent for this correction. He who is best qualified to offer such, will be most indulgent to the mistakes of this kind which require correction. The number of provincial expressions which are found in all agricultural writings, render translations from one language to another very difficult: and this difficulty may well be conceived by all readers who have noticed how many of the provincialisms in our own language are unintelligible. Neither the verb "muter', nor its derivative "*mutage*" can be found in either of five French dictionaries in our possession—among which is the old voluminous *Dictionaire de l'Académie, &c.* a modern abridgement of the same, which professes to give terms of science and art, and Rozier's *Cours Complet, &c.* one entire volume of which is occupied with definitions of technical and provincial terms.]

For the Farmers' Register.

THE SOILS AND AGRICULTURAL ADVANTAGES OF FLORIDA.—No. 2.

Plantation Wascissa, Florida, July 2, 1835.

The most prominent characteristics of the lands immediately bordering on the Atlantic in East Florida, were succinctly delineated in my last letter: and conformable to my self-assigned order of correspondence, I continue my observations on the remaining and extensive inland portion of the "eastern district."

The character, features, and growth of the land are singularly and abruptly changed, as we proceed westward from the ocean: the country becomes generally more interesting in landscape, and more diversified in soil and native production. The monotonous levels and eye-fatiguing flats of the low Atlantic marshes, are no longer, with their rank grassy plumage, and thirsty palmettoes, to be seen: dense and towering forests of every foliage, luxuriant over a rolling and picturesque country most verdant with herbage, and spotted like the variegated leopard, with abrupt and strange marks of richness and sterility, strike the observant traveller with surprise, not unmixed with the illusion of enchantment.

The river Saint John's, than which there can be no nobler stream, seems by nature intended as the marked and eternal division of this varying and diversified country. It rises amid the swamps of the Everglades in the far south, and with comparatively little deviation from a north course, it streams itself along for an hundred miles and upwards, receiving numerous tributaries, and rapidly becoming a wide, magnificent river. When reaching the site of the town of Jacksonville, some twenty miles from the sea, it gracefully rounds and empties its widened breadth almost due east, into the ocean. This river is singularly characterized, in addition to its unrivalled forest banks, by extensive eye reaches, and prospective scenes, in being the only river of magnitude in the southern states of America that, from its source to the parallel of its mouth, runs *northerly:* and still more is it notable, that with this course, it should run for nearly one hundred and twenty miles of its length directly *parallel* to the Atlantic, and only divided for that whole distance, from the oceanic waters, by a narrow strip of land some thirty miles in average breadth. It is indeed a great natural canal, singular in its position, and unsurpassed in magnitude; and one sighs in witnessing the unprofitable waste, and sluggish idleness of its magnificent waters. The curiosities of the Saint John's are likewise peculiar, and well worthy of sight. I would name the *Silver Spring*, so dazzling with its transparency and spangled carpet, and so enormous in its dimensions and vehemence: as also the *Golden Spring*, equally curious, though smaller, in its jewelled bowl, and pellucid waters: but above all is most remarkable the phenomena of sound to be here awakened: no where can

"Gamboling echo hold more boisterous court—"

than o'er the still expanse of this enchanting stream. The report of my rifle was reverberated with astounding loudness, and stammering reiteration, alternately from bank to bank (here five miles distant) in thirteen distinct successions, gradually diminishing in power, till

"Distance smothered softly the sound."

Crossing this fascinating river, as the line of our descriptive sketches, we leave in the east the Atlantic, with the lands delineated in my first letter, and we find on the west the forest of Alachua, now to be described.

The county of Alachua extending nearly from the western bank of the St. John's, to the gulf of Mexico, and between latitude 29 degrees and 31 degrees, as its average northern and southern boundaries embraces an immense body of rich and diversified lands, constituting it one of the largest and most valuable counties of the territory. It is as yet but thinly populated: the presence of the Seminole Indians, heretofore in sole and native possession of its wide extending hunting grounds, has prevented the settlement of white men. These ill-fated sons of the forest will however *"relinquish"* their original rights this winter, and remove to the "far west," there to await the sure advance of demoralizing civilization, and as surely, their *second* pilgrimage! Speculation and avarice have, notwithstanding the "red men," ere this found a limited "local habitation" within these Indian reserves, and from the exciting reports, the tide of emigration is now setting rapidly thither.

A great diversity of soil, as visibly marked by an infinite variety of growths, necessarily is to be found throughout so extensive a county. The most valuable is the dark chocolate soil, generally on tabular sites, but oftentimes over the rolling lands, indicated by a dense growth of sweet-gums, dogwood, and tulip tree, with an impenetrable undergrowth of gigantic grape vines, thickets of wild orange, and plum. This soil I have never had an opportunity of examining accurately. To the eye, touch and taste, it seems composed of a strong rank vegetable decomposition, coating the surface in black humid fibrous matter, and combined with a large portion of aluminous earth, containing lime or other salt in visible quantity, though not in a carbonate combination. These lands when first brought in tillage yield but indifferently well, being, in the language of the district farmers, "too luxuriant and fat, and produce only weed." Cotton, corn, and sugar, however, after two or three years' culture, produce amazingly, and continue their large returns as far as experience has yet gone. I have said that "lime is present, though not as a carbonate," in these soils. I may extend my remark, and doubt whether calcareous earth as carbonate of lime is to be found in any of our inland districts: they have undoubtedly lime in abundance, and in some places are based on rotten limestone; yet I am inclined to think we have the combination of the sulphate, instead of the carbonate—and most probably more of magnesia, than of lime. I hope however ere long to analyse these interesting formations, and place my knowledge beyond an hypothesis. My present conviction is partly formed, by the taste of the earth, and partly from the great luxuriance near these rich mulatto soils of towering pine trees! But to return. These rich soils are beyond doubt inexhaustible; and large tracts are now vacant, awaiting the test of culture. Some portions are lighter in color, showing the preponderance either of silicious or magnesian earth: but all are proverbial for fertility and strength. The attention of the scattered settlers has heretofore been devoted to grazing: and their extensive herds, well rounded in limbs, and accompanied with numerous young, afford substantial evidence of the profit of such occupation. Some few plantations have been opened, and are now successfully under cultivation of the sugar cane, sea island cotton, and farinaceous grain. Their crops have been variable in production: though their failures may justly be attributed to the deficiencies of the requisite machinery and dilatoriness in harvesting, rather than to any fixed discovered error of soil. Procrastination has been here, as well as in other parts of Florida, the thief of wealth. Col. Clinch of the army, is I believe, the proprietor of the largest settled estate in Alachua. His plantation has been in operation for several years, and though it has had, like others, its good and bad crops, it may be stated, (in evidence of what the soil and climate can produce,) that last year, notwithstanding the unexampled severity of the winter, he realized from his crop, unassisted by artificial manuring, and at best roughly cultivated, with only about fifty negroes, the sum of (as understood,) $20,000! having made (as heard,) 170 and odd hogsheads sugar, and 60 odd bales of fine sea island cotton, besides a large crop of corn and other provisions!

No other evidence is needed to establish the great fertility of the Alachua soil; or to show the immense returns capable of being there made from agricultural investment. What one man *has done*, a thousand equally skilful and industrious *may do*: and if any apology is due for the freedom with which I promulgate private emolument, I trust it may be found excusable, in the absence we have of *other* means of comparing the fertility and capabilities of this new country; as well as in my aim, that the speculative world may be attracted to an examination of this wealthy, yet vacant land. The advancement of the public weal augments the prosperity of individual interest; and upon this truism, I hope yet to see intrusive and prying science embowelling the concealed mines of Florida.

Alachua has, bestowed by nature, a liberal share of her best advantages. With an extent of latitude, embracing both a temperate and tropical clime; and affording a *choice* of navigation and intercourse, either direct to the gulf of Mexico, (of which it constitutes a part of its eastern boundary,) or through the tributaries of the St. John's River, to the Atlantic. With a soil rich beyond exhaustion, rich in perpetual pasturage, and valuable timber, and varied in texture and qualities; congenial to the production of almost every northern and southern staple of commerce. With open and commanding roadsteads, among which are notable Charlotte's Harbor and Tampa Bay, equally proverbial for good anchorage, accessibility, and uninterrupted health. All these are advantages singularly combined, and which must not only create rapid wealth and improvement, but ultimately rank the County of Alachua as the "*Jewelled Queen of Florida.*"

My next letter shall not be so prolix, and will be upon the Middle District.

FARQ. MACRAE.

For the Farmers' Register.

VEGETABLE AND ANIMAL ANALOGY.

[Continued from page 756, Vol. II.]

Observation teaches that nature has implanted appetites as various among vegetables, as we find in the animal kingdom, and hence arises that endless diversity of their qualities and properties. They are so differently organized, and had implanted in them originally, such various appetites, that every order and species of the two kingdoms may receive certain principles from the earth, which when combined in certain proportions, shall constitute the animal or vegetable; and although they may be equal in size, and similar in their general conformation, as to external appearances, and nourished by the same food, shall differ in strength, texture, and solidity. This, however, can only be explained upon the principle of a difference in organization; viz: a difference of capacity in their vessels, glands, &c., whereby certain portions of the same food are received, or rejected, according to the structure of those parts, or capacity for receiving suitable proportions of aliment. A plant extracts from its gross parent (the earth) those principles which are suited to its nature and constitution; the earth always ready to give, but the plant is not willing, and rarely receives any thing but what is proper for its subsistence: it is worthy of remark, that in soils most favorable for the production of the various mild esculent or nutritive plants, *nicotiana, cicuta, hyosiamus, digitalis, lauro cerasus, datura stramonium, monkshood*, &c., flourish and arrive at great perfection. There can be no doubt that the principles received from the earth, by those noxious plants which constitute their most virulent and active qualities, are not intimately blended with that which affords nourishment, and becomes a component part of all the nutritive tribe. Their organization, or the capacity of their absorbing vessels, are such as necessarily exclude those poisonous principles; and it seems that by virtue of an inherent or instinctive principle implanted in them by the author of their existence, those offensive matters are uniformly rejected. From this circumstance may we not infer, that both the animal and vegetable kingdoms possess the power of receiving food when it is offered them, and also the faculty of choosing. Animal and vegetable instinct may probably be admitted, since we cannot with greater propriety call that principle of a child by any other name, which prompts it to seek the breast of its mother, soon after it comes into the world; and that of aquatic fowls to seek water, as their natural element, soon as they are disengaged from the egg-shell; and that of a vine to rear its head to the highest places, and entwine every branch within its reach, as if mindful of the danger to which it must be exposed, if spread out promiscuously upon the earth. Many other circumstances relative to vegetables, would, at first view, seem to prove that they possess sensitive and instinctive qualities, not unlike those of animals.

The vegetable and animal kingdoms derive their support either directly or indirectly from the earth, through certain media. Many of the large vegetable seeds, when divided longitudinally, present an entire plant with its stalk and foliage complete in miniature, and nothing wanting but to be placed in reach of what it is destined to receive for its further developement. We may perceive at the same time, that this little germ has a partial connexion with the farinaceous matter which protects it, at this early state, from external injury, till, like the chick confined in its shell, which has exhausted the resources of its confinement, and arrived to that degree of maturity which enables it to sustain the impression of the earth and atmosphere, it bursts forth and seeks new acquisitions in the earth. It is probable that this germ is nourished, and thus far developed, by the channels of its connexion with the farinaceous matter which forms the body of the seed: yet from some experiments made with the bean, it seems that the germ, so far unfolded as we find it in the ripe seed, is not necessarily dependent on those channels through which it had previously received its nourishment, for a final germination in the earth. This farinaceous matter may be separated and removed without the least injury to the plant, and this too before it has rooted. On dividing the two tables of the bean longitudinally, we perceive the germ pretty firmly embraced by each of them, forming a sort of cylindrical mein or link of connexion, which is merely partial or temporary, for those two bodies, though lively and juicy at an early stage, wither and fall off at a certain period when the plant has put forth roots and leaves; which circumstance inclines me to be of opinion, that they serve some useful purpose in the way of assimilation or transmission of suitable juices for the nourishment of the germ—though this may also be rendered somewhat doubtful from the following experiment. The germ was carefully detached from the two tables of the bean, having previously provided a suitable space for its reception by hollowing each of them: this was done in such a manner as to free the entire germ from any degree of pressure that might be made on it by the two sides of the bean, when they were brought in contact—having bound them pretty firmly together and placed the whole in moist vegetable earth—on examination the third day, the germ had become so enlarged, as to put the bandage very much on the stretch. It was now removed from the tables of the bean and placed naked in a fine bed of earth which had been prepared for asparagus, where it soon rooted and flourished as an ordinary seed would have done in its natural state. Hence an inference may be drawn in favor of the opinion, which supposes the fœtus receives no nourishment by the umbilical cord. Nevertheless, I am well assured that the seed of vegetables as well as animals, receive their nourishment through the channels I have mentioned, during their attachment to the parent.

I am unable to conceive how nourishment can be conveyed to vegetables, if the mouths or extremities of those vessels which open on the surface of the roots, be quiescent. Capillary attraction above would hardly convey the necessary principles to the different parts of the vegetable. If it be not allowed that those vessels possess irritability and contractibility similar to those of animals, the whole process of vegetation must be performed mechanically. It must be explained upon the supposition, that a partial vacuum is formed in their vessels, or the fluids they contain become rarified, or less dense than those which are afforded by decomposition in the earth, and brought in contact with their rooty fibres; if this be the case, those fluids, according to the general laws of gravitation, must press forward and occupy the void spaces. But I think it much more probable that these vessels possess excitability or aptitude of motion, and perform their office similar to the lacteal and lymphatic vessels of animals—their food as it is offered by the earth, being in a similar state to that of animals as it is found in their digestive organs, where the mouths of the lacteal vessels are open to receive it for the nourishment of the general system.

There seems to be a remarkable similarity in many of the operations of nature, and it is this obvious analogy, discoverable in the astonishing works of creation, that gave rise to the opinion, that it is not more necessary for a continuous route of circulation to be kept up between the mother and fœtus, in order to produce its evolution, than that the earth should be considered organical, and continuous vessels form between it and vegetables at the time of their germination, for the purpose of conveying into them the various matters of which they are formed. A tree acquires from the earth its cortical and ligneous parts, without a placenta to assimilate, or an umbilical cord to convey to the general system; and is on a footing with an animal which is disengaged from its mother, and seeking food in the earth where it may be found. The general operation of nature, as it regards the production and nourishment of the two kingdoms, is decidedly analagous, with this difference, that animals receive their food somewhat refined and assimilated, while the vegetable kingdom extract it from the crude matters of the earth.

In order to pursue the analogy between animals and vegetables with perspicuity, we should consider the fœtus entirely distinct or unconnected with the mother; or rather as having no further connexion between them, than that which may be dissolved without causing a solution of continuity; or perhaps it may be admitted with some plausibility, that they are connected in a manner similar to that in which the various vegetable seeds are to their mother stalks previous to their maturation: at which period we observe the temporary union is dissolved, and they fall off spontaneously. It is not until they have arrived to this state of maturity and independence, which prepares and enables their delicate organs to receive nourishment directly from the earth, that they are disengaged from their maternal dependence.

In like manner, the female of the animal kingdom, when pregnant, may justly be said to bear seed, which become ripe at the usual period of parturition. At this crisis the temporary union of the placenta, with the uterus is dissolved, and the fœtus ushered into light and life.

GALEN.

REPLY TO "COMMENTATOR'S" REMARKS ON GALEN'S COMMUNICATION.

To the Editor of the Farmers' Register.

I have seen in the 12th No. of your Register, Vol. II, "Remarks on the papers contained in No. 9 of the Farmers' Register," by "Commentator." I beg leave, Mr. Editor, to subjoin a few of his remarks. "With Galen's communication, I was, upon the whole, much pleased; although I must say, that he delivers his opinions—however important the subject, rather too abruptly. For instance, he asserts—without the slightest doubt or qualification, that as to plants, "the earths afford no real nourishment themselves, but act entirely as exciting agents." Now, do not all agriculturists admit that there *is* such a thing as *the food of plants*, and that it is supplied either by *the earths*, or *by water*, or *by both?* Will they not also admit, that "exciting agents" cannot, with any propriety, be called suppliers of food? Where then is Galen's authority for assuming *that* as a fact universally admitted, in support of which, he offers nothing, but his *ipse dixit?* His concluding sentence furnishes another instance of a highly important assertion, entirely without qualification, or illustrative argument to sustain it. I subjoin his own words: "There is a wonderful similarity between the vegetable and animal world; they are both governed by the same laws—the various agents that act upon them are similar," (to both these assertions there are numerous and striking exceptions,)—"their organization in many respects the same, and they both possess motion, sensation, and life." This last assertion also, is much too broad; for, not to cavil at the term, "possess motion," instead of the power of motion, the motion and sensation ascribed to vegetables are as really unlike the motion and sensation of animals, as any two things can possibly be, between which any sort of resemblance has been supposed to exist. Such fanciful analogies may do very well as ornaments of style, but not for scientific agriculture."

"Commentator" thinks I have delivered my opinions "rather too abruptly"—be it so. I wish, however, to be particularly understood, and if "Commentator" has read my communication in the February No. of the Farmers' Register with attention, he will do me the justice to say, that I confined my remarks to the simple or primitive earths, viz: silex, lime, magnesia, alumine, and barytes, and not to compound earths containing foreign or extraneous matters. With all due respect to the opinions of "Commentator," I must be permitted to remark, that I have been educated to believe, and do now believe, primitive earths afford no real nourishment to plants, but act on vegetable and animal matters, hastening their decomposition: and the principles arising from the decomposition of water, air, vegetable and animal matters, feed and nourish plants. If the food of plants is supplied from primitive earth, why the necessity of adding manure? Seed, deposited in silex, lime, magnesia, alumine, or barytes, may possibly germinate, and live until the germ has devoured its farinaceous matter, but they cannot possibly mature with all the atmospheric air and water that can be given. This I suspect "Commentator" will admit, and if admitted, would it not be fair, at least, to infer that they do not contain in themselves any nourishment, but act on foreign agents as stimulants or excitants? "Commentator" asks this plain question, "now, do not all agriculturists admit that there is such a thing as the *food af plants*, and that it is supplied either by the earths, or by water, or by both? Will they not also admit, that 'exciting agents' cannot, with any propriety, be called suppliers of food?" Yes, all agriculturists must admit that there is such a thing as the food of plants, but I am strongly inclined to think, *all* will not admit that it is supplied by the primitive earths. Again, I take leave very respectfully to remark, that "Commentator" is mistaken if he is under the impression that I have stated exciting agents are suppliers of food—I have not, nor did I intend to convey such an idea; I merely stated, that earths were exciting agents—lime, for instance, acts upon straw, or some extraneous matters, and becomes the exciting agent in their decomposition.

With regard to my concluding sentence, which seems to "Commentator" so very objectionable, I believe philosophers of every age have thought with me, or perhaps I have thought with them, that "there is a wonderful similarity between the vegetable and animal world, &c." Yes, the various laws and agents, I think, are similar, for they are both acted upon by similar causes, viz: light, heat, air, water, food, &c.; and I might add, that both kingdoms are surrounded by ten thousand irritants, that act upon, and effect them in a similar way.

I believe vegetables not only have the power of motion, but possess motion in some degree, and I am not alone in this belief. Many plants are said to recede from the approach of the finger, and we have all seen the tall sun-flower turn to the *great luminary*, face to face, and follow him throughout the day. With respect to vegetable motion and sensation, I do admit it to be very *unlike* the motion and sensation of animals. As it regards "fanciful analogies," they are common, quite common: perhaps they are to be found in some of the "Remarks on the papers contained in Nos. 9, 10, 11, of the Farmers' Register," my "*ipse dixit*" to the contrary notwithstanding. I am much pleased with "Commentator's remarks," and regret that he did not commence with the first Vol. of the Farmers' Register.

GALEN.

The following letter was evidently written as soon as the article referred to had been read, and before noticing that the earlier piece of "Viator" had been discovered and republished in a later sheet of the same No. But though the first purpose of our correspondent has been anticipated, his after observations are not the less interesting and deserving of notice.

ON MILKING COWS.

To the Editor of the Farmers' Register.

Baltimore, July 3, 1835.

I was much pleased this morning with the article in your July No. on the spaying of cows, and write this note merely for the purpose of putting you in possession of the information necessary to complete the historical part of the discovery. In Vol. XIII, page 53 of the *American Farmer*, (April 29, 1831,) you will find an article copied from the New England Farmer, signed "Viator," which contains the first and only record of Mr. Winn's experiments. It is undoubtedly the article from which the French obtained the suggestion; and this will not appear strange when it is recollected, that the American Farmer was regularly received by one or more of the agricultural societies of France, by Lafayette, and several others. I have full confidence in the success of the experiment, if fairly and properly tried; but have endeavored in vain to induce persons having the means to make the trial. Indeed I have not been able to find any one who could perform the operation. As you have the American Farmer to refer to, I have thought it unnecessary to copy the article. By the way, I had almost forgot to state the cause of my pleasure on reading your article: it was with the very excellent directions given in it by M. Levrat for performing the operation, which will enable almost every one, of *nerve*, to spay a cow. I should much prefer throwing the cow down on her right side, with her head declining upon the side of a moderate hill obliquely downwards, her back towards the declivity. But probably the best fixture would be the *gallows*, or frame, in which the smiths sling oxen for the purpose of shoeing.

Much of the advantage of spaying will of course depend upon the previous management of the cow. A good cow, of almost any breed, may be secured by proper management with the first and second calf. The young cow should have plenty of good pasture, pure water, and salt, regularly; then, if she be not allowed to suckle her calf, after the udder shall have become healthy, (generally three to seven days after calving,) if she be regularly and *thoroughly* milked at six in the morning and six in the evening, I would be willing to warrant her to become a first rate cow when she has her third calf. It is as important that a cow be milked regularly as to time, as it is that she be properly fed. Nature accommodates herself to all our practices, provided they be not unreasonable: but she will not be trifled with. Therefore, if a cow be allowed to suckle her calf, she gets in the habit of secreting a certain quantity of milk every half hour or so; and when the calf is weaned, we cannot correct the habit so as to adapt it to the required milking every twelve hours: therefore, the calf should not be allowed to run with the cow at all; nor to suck her, after her udder is in order. Neither should we be careless as to the times of milking. The day should be *equally* divided, else between the morning and the night milking, there will be fourteen to sixteen hours, and between the night and the morning there will be only eight to ten; and the consequence will be, that nature will be baffled in her regulations of the animal's habit, and she will be injured as a milker. Now, if a cow has had all this previous care and attention, she will, four weeks after her third calf, come to the pail with a full bag of milk, and may then be secured as a permanent milker by spaying; as I verily believe, both from the facts stated by "Viator," and the experiments of M. Levrat, and from the reasonableness of the theory. I hope some of your friends will try it.

When I began to write, I only intended to inform you where to find the record; but my pen has run wild. When I get upon a subject of this kind, I never know when to stop.

GIDEON B. SMITH.

ANTHRACITE ASHES.

The *Philadelphia United States Gazette* says, "a lot of land, clay and sand, was covered over with ashes from anthracite coal, and clover seed sown upon it in abundance. The clover after waiting a little while longer than usual, sprung up like an ill weed, and about two weeks since presented a luxuriance of growth exceeding any thing of the kind we ever saw. The clover had the appearance of tall pea vines, so rank had it shot up. If anthracite ashes have such virtue, it would be well for the public generally to understand it."

From the New England Farmer.

SCRAPING FRUIT TREES.

East Hartford, June 15th, 1835.

Dear Sir—I have for the two last years scraped my apple and pear trees towards the latter part of June or commencement of July, and think from the experiment it is much the best season to scrape the ross from the body and large limbs of fruit trees, I have ever tried. I prefer to scrape them with a hoe soon after a rain, as they scrape much better when moist.

It is well known that many apple trees bleed, turn black, and are much injured, when scraped in the spring season. I knew it was the rule with some farmers (if they had a tree in their orchards that was unthrifty, or was not good to bear) to peel off the whole bark from the body of the tree during the longest days in June, and that a new bark is soon restored at that season. If the trees are scraped abundantly, and some of the bark entirely torn off, they heal immediately and do not bleed. I cut several decayed limbs from one tree two years since, which healed over much better than when trimmed in the spring. I think the fruit on those trees scraped in the above manner much improved in size, as well as in the general appearance of the trees.

"FLORIDA COFFEE."

To the Editor of the Farmers' Register.

Early in May last I had an opportunity, for the first time, of seeing some young plants of what has been called "Florida coffee," from which I was satisfied that it is not *okra*, and that it is probably a species of *cassia*, several of which are natives of the southern states, and are particularly abundant in Florida. This opinion I expressed at the time in a letter to you: and I perceive from an article in your June number, that it is confirmed by Mr. Herbemont, who states that is a *cassia*. When the plants which Mr. H. is cultivating shall have been fully developed, he will no doubt be able to ascertain the species, and thus we shall arrive at a knowledge of the true nature of the plant.

H. E. C.

June 20th, 1835.

COTTON SEED AN ARTICLE OF FOOD.

To the Editor of the Farmers' Register.

It was formerly said that in some of the southern states the negroes were fed on cotton seed. In this there was no truth whatever. I was therefore not a little surprised when I read (in the Encyclopædia of Plants,) that cotton seed are used in the south of Europe, by the poorer class, as an article of diet. As they have none of "Follett and Smith's Hulling Machines," it would be curious to know how they dispose of the outer covering of the seed.

H. B. C.

For the Farmers' Register.

NOTES OF A HASTY VIEW OF THE SOIL AND AGRICULTURE OF PART OF THE COUNTY OF NORTHAMPTON.

The county of Northampton, which forms the lower part of the peninsula called the Eastern Shore of Virginia, presents a remarkable appearance of uniformity, in the level surface and general qualities of the soil, and in the mode of tillage and general management. The land has but little elevation above the water which almost surrounds it; and the level of the surface is rarely changed so much as to effect tillage or labor injuriously—and nothing deserving to be called a hill is found any where, unless the abruptly rising (though low) borders of creeks be so designated. The soil is universally sandy, and differs very little in texture or appearance, and is not more than three or four inches deep. On the bay side, below the sandy subsoil, there is generally a yellowish clay, lying from twelve to sixteen inches below the surface, and which is open enough to permit the filtration through of rain water. Below the clay is a barren white sand. The clay is generally deficient entirely elsewhere, or is not found within several feet of the surface. The rate of fertility, though made different by nature, and still more so by the difference of treatment under tillage, is yet more uniform than any other considerable tract which I have observed. No one acre seems to have been very far below the medium grade of natural productiveness, and not many are very much above it. No land was seen which appeared half as rich as the best soils west of the Chesapeake—and none as poor as the worst—which are far more abundant than the rich, on both sides of the bay.

Flat and narrow as the county is, (the mainland varying between two and eight miles in width,) there is a central ridge of a little more elevation, and of worse and poorer soil than the lands on the bay and the sea side. Of the two last, the lands on the bay are generally the best. But a very large proportion of all the lands lie on the bay and the Atlantic Ocean, or on the creeks and inlets. It is said, that there are very few farms in the county distant more than a mile from navigable water. This is an immense advantage enjoyed by the farmers—and another connected with it is, that every Atlantic market is open to their choice. A string of long, narrow and low islands, barely separated from each other by inlets, serve to protect the mainland from the fury of the ocean, and in the navigable sounds, between eight to twelve miles wide, keep comparatively smooth water, when the wind is producing awful effects at the distance of but a few miles. These islands are part of the chain which reaches from Florida to Delaware, and offers between it and the mainland, a safe inland navigation for stout sea vessels, which is scarcely interrupted by too shallow water, or too open sea, during the whole distance.

The waters bordering on and intersecting Northampton, are not more valuable for navigation, than for furnishing in great plenty and variety, fish and wild fowl. The greatest delicacies for the table which salt water yields, are here common and cheap: and coarse fish, which are prized in our fresh waters, are here caught in such numbers, that they form a valuable resource for manure, which a few enterprising farmers have already begun to profit by using.

Though the soil is sandy, and almost universally so, it is less so than is generally reported. I saw but little land that seemed as sandy as much of the county of Surry—and the greater portion of the soil is not more sandy than part of Lower Weyanoke in Charles City, the farm of the late Fielding Lewis, which, since being limed, is so productive under wheat, as well as in the crops more suited to light land. Yet scarcely any wheat is made in Northampton—and from the very few trials of this crop on a small scale, it has been decided generally, (and no doubt correctly,) that the soil is quite unfit for the profitable growth of that crop. The use of lime, or other calcareous manure, would probably remove the existing obstacle to wheat culture: though even then it might not be so profitable as the crops now preferred. Wheat has been often raised with sufficient success to encourage the farmer to persevere in the culture. But he has invariably found that there was a great diminution of product when wheat was sown a second time on the same land, in its proper turn in the rotation. I have heard of a like result on the sandy land of Sussex, as ascertained by two rounds of the rotation of a very intelligent practical farmer.

The rotation of Northampton, which may be almost said to be universal, is 1st, corn—2nd, oats—and so on every year as long as cultivation is continued on the same land—and that has been known to be, on some fields, and those never manured at all, for more than sixty years. The only material variations are in the management of the land in the interval of time between reaping and stacking the oat crop, and ploughing the land in the next winter, or early part of spring, for the succeeding crop of corn. Some very few farmers permit no grazing: a greater number graze during that whole time, but not so closely but that much of the volunteer growth of vegetable matter remains to be turned into the earth by the plough. The others, and they are the far greater number, graze as closely as can be done by all their live stock. Some even believe that the closest grazing is most beneficial, and leave the fences down that their fields may be a common pasture for all the roaming stock of the neighborhood, between the removal of the oats and the beginning of preparation for corn. Ten or twelve years continuation of this latter practice, in at least one case, has not served to prove so satisfactorily, to the individual who has pursued it, the evil of the practice, as to put a stop to it. But the grazing in general, is not so close as might be supposed from the unrestrained access of each farmer's live stock, because their number is kept small by the nature of the land and mode of tillage. There is but little grazing land before the oat harvest—and the products of live stock, as well as their numbers, are smaller than usual elsewhere. This fault in their husbandry, (as it may be considered in one respect,) perhaps has saved the fields from exhaustion.

Whoever may for the first time hear this rotation described, will be ready to pronounce it as having been devised and commenced in ignorance, and carried on in direct and manifest opposition to all the established principles of agricultural science—and that persisting in it for any considerable time, must always be unprofitable to the farmer, and result inevitably in the destruction of the fertility of the soil. But strange as it may appear that such a rotation should be in general use, it is still more so, that it should be maintained by the general, if not universal testimony of the inhabitants, that the production of the county, for the whole space under tillage, has not been diminished under this system—that the exhaustion of particular farms when worst managed, has neither been rapid, or considerable, in any short term of years—and that when attention has been paid to collecting and applying manures, and grazing has been prevented, the most enlightened farmers concur that the rotation, so aided, has been found to increase the crops regularly, and for a long term: in short, that the rotation is decidedly an improving one, when judiciously conducted; and most probably that it is better for the farmer than any other more conformable to the generally received opinions on agricultural improvement. It must be at least admitted, that many and strong facts, and those tested by long experience, are brought to sustain the superior advantages of the Eastern Shore rotation.

There is one additional feature of the tillage here, which in many cases has had much influence in aiding the benefits, or lessening the scourging tendency of the rotation. This is the growth of a plant which has great value as an improver of fertility, and which is peculiarly adapted to sandy soil, and to the succession of crops here in use. The Magothy Bay bean is a plant of the pea tribe, and the whole of that tribe seems to possess greater power than any other for acting as manure. Clovers are of the pea kind, and red clover stands at the head of the class of green manures. But though a good cover of Magothy Bay bean is probably of far less value as manure than a good cover of clover, yet the former growth in general is more valuable, because requiring no regular sowing, but very slight care for its perpetual preservation, and producing crops far more luxuriant than could possibly be obtained of clover, and perhaps of the most worthless weeds on the like sandy soils. The seeds are very hard, and slow to vegetate, and will remain sometimes for years in the soil before sprouting. This quality prevents the tillage of corn, however perfect, serving to root out, or materially thin the after growth. The spring ploughing for oats retards the springing of the plants, until the oats are enough ahead not to be injured by the undergrowth of beans. At this time, (July 10th,) the reaping of the oats is generally going on, or has been just finished where most forward. The undergrowth of Magothy Bay bean is from three to eight inches high, according to the condition of the land, (rarely more than six inches) and is not a material impediment to reaping and saving the oats. It is even now a beautiful growth—but its present appearance is nothing in comparison to what will be exhibited in August, and from that time to frost, according to the descriptions given of the well covered fields, and which I can well believe from the more sparse growth which I have seen matured at home. The flowers are very abundant, and of a deep and beautiful yellow—and continue to open for many weeks. The whole plant was well described by Bordley, as a "Lilliputian locust tree," with which it agrees in the general form of the flowers and leaves. The beans rise rapidly as soon as the shelter of oats is removed, and acquire a height usually varying between one, and two and a half feet, according to the land. Even where no care whatever is taken to preserve the succession of plants, and indeed where the tillage and grazing (under the common rotation) is such as would effectually destroy any other kind of any value, this continues to be the most general cover of the land after the oat crop—though, of course, a scattered and thin cover compared to what is found under more favorable circumstances. Cattle feed on this plant, and indeed find not much else in the fields, after the scattered oats have been picked up. Hogs strip off the green pods, and to the extent of their operations, destroy the seeds. When matured, the seeds are so hard that they would probably pass through the body of an animal uninjured. The plant is an annual. The leaves fall before winter, and the stalks seem so hard, that many persons would on that account deem them of but little value as manure.

In the few cases where the land is not grazed at all, and even where the small number of the farmer's stock prevents much of the bean cover being taken off, it is evident that there are sufficient means afforded to preserve the succession of the growths of this plant. Where several successive hoed crops, or other circumstances, have thinned the bean cover, it is easily increased by a means used by those who attach proper value to this improving crop. Numerous plants spring up in the land under corn, which are generally, of course, destroyed by the ploughing of that crop. But near the plants of corn, some bean plants will grow out of the way of the plough: and as but little hand-hoe work is used, or required, the neglect of weeding, as well as the design of spreading the growth, serve in this manner to furnish numerous seeds to be added to those then buried in the earth, and which will spring the next year.

Where the land is not grazed, or even when the grazing is but slight, the Eastern Shore rotation, though nominally the same, is in truth altogether different. It then consists of a regular succession of *three* crops—corn, oats, and Magothy Bay bean—the last being a *crop of manure* regularly turned in to sustain the land under the two succeeding grain crops. This improved practice would take away the objection to the perpetual succession of grain crops—and presents a rotation perhaps as conformable to sound theory, and furnishing as large a supply of food (*grown on the land*) for plants, as is found in the best modern practices under what are called three and four-shift rotations. The circumstance that this three-shift rotation has only two years' length, is decidedly in its favor. If all other things are equal, and an equal proportion of the rotation is of meliorating effect, the more crops that it will furnish the better, within any certain term of years. One of the greatest causes of the superior productiveness of the farms in Flanders, is found in the frequency of secondary crops, by which two crops are obtained from the same field in one year. The great objection to such cropping in this country, is the amount of labor required at very busy seasons, and that the low price of land offers no inducement for such perfect tillage. But the secondary crop of the Eastern Shore rotation requires no trouble or cost of preparation or tillage—and therefore may be used to the greatest advantage where the peculiarity of soil favors the growth of the Magothy Bay bean—and forbids (as is supposed to be the case here,) the adoption of other courses of crops, which would be incompatible with the growth of that valuable plant.

It may be asserted then, according to the foregoing views, that the mere difference of using this green crop directly as manure, or for grazing, will serve to place the usual tillage of this country under a mild and improving rotation—or under one which, though it seems not to be ruinous *here*, well deserves to be so, and would be so, I think, on any other land to which my labor, or personal observation, has been directed. And why it should be otherwise here, I cannot hear or conceive a satisfactory reason, though the fact is readily admitted to be true. The reason which is generally assigned for the sandy soil here bearing up so long under the worst use of the corn and oat rotation—and for being actually improved under its best use—is the beneficial influence of the air, which is supposed to be loaded with salt vapor from the adjacent and almost surrounding waters of the Chesapeake and the ocean. Without discussing the truth of the fact of salt being thus continually conveyed to the soil, it seems incredible that salt in any quantity can act as an alimentary manure to grain crops, or perpetually renew the whole or any portion of the wasted fertility of soil. From time to time, persons have discovered great value in salt as a manure—and much more frequently its use has been found of little value, when not decidedly injurious. But the most sanguine advocates for the use of salt as manure, have not supposed it to give *directly* food for plants, as dung does, or as being a manure which by annual repetitions can possibly continually renew the productive power of land. If this were so, surely men might copy nature's practice in this respect, and wherever the price of salt did not forbid its use, inexhaustible fertility might be produced and maintained. But I cannot think that any vapor, salt or fresh, can be serviceable to grain crops, except as furnishing additional supplies of moisture: and this effect, though highly beneficial to grass crops and grass husbandry, when considerable, is at least of very doubtful advantage to grain crops.

But I repeat that there is no question of the great power of these lands to resist exhaustion under a scourging and barbarous course of tillage—nor of their fitness to be easily and profitably improved by the best practices already (though rarely) here in use. I do not rely for this conclusion on the experience of any one farmer, however intelligent and well qualified to judge, and however much entitled to command belief, and the utmost respect for his opinions—nor on the state of any particular farms, long kept under either good or bad culture. I have heard many proofs of these kinds which might be adduced by others. But my cursory views and hurried inquiries having been limited to but a few days of personal observation, they were not sufficiently accurate for such detailed statements, even if that course were not forbidden by the length to which they would extend this sketch. Such details, however, from those possessing better means for observation and the collection and comparison of facts, would be highly valuable and interesting—and it is earnestly hoped that such will be given to the public at a future time, by one or more of those better fitted by their location for the task. If I can attract attention to subjects which deserve it, and induce any others to furnish more accurate information, my end will be accomplished: and even the inaccuracies, or unintentional misrepresentations, which my very imperfect notices may perhaps exhibit, will not be regretted, if other persons should be thereby drawn forth for their correction, and to supply the more numerous deficiencies. This has been the motive of my offering such hasty and imperfect observations, and must serve as my apology for doing that which in general ought always to be avoided—that is, writing and publishing opinions on subjects that we know very little about. But by such means, in several former cases, very valuable and interesting communications have been elicited from others, and discussions have been produced which have shed much light on agricultural practice and opinions. To similar effects, I hope these imperfect notes may be the humble instrument of impulse.

To return to general results. Very little land in Northampton, compared to the mainland of Lower Virginia, has been "turned out" of cultivation, because exhausted, to grow up in trees. And where this has been done, though of course the most impoverished land was so treated, the motive was in part to permit pine timber to grow, to supply the place of that which was taken off from the small amount of woodland on the farm. Wood and timber are very scarce, and but little land is given up to even the growth of what they have, which is unfit for building purposes, and but of small value for fencing or fuel. The extensive clearing and destruction of good timber has been caused by the demand for land for cultivation, and encouraged by almost every acre of dry land being fit and profitable for the plough. I have seen scarcely any land recently "turned out:" and all which has been at any one time thrown out of cultivation—admitting all to be on account of extreme poverty, and for the purpose of being recruited in fertility under pines—must be inconsiderable. Therefore the continued productiveness of the county in general, cannot be materially aided by this cause. Neither is it to be attributed to the great and profitable improvements made by particular individuals, by means of using manures not derived from their own fields, whether putrescent or of a more permanent character—for these examples have, unfortunately, been too few to have a considerable effect on the general products and profits of the county. The lands which have produced nine-tenths of all the grain in the county, and those which now produce as large a proportion, probably may embrace not one farm which has been so badly cultivated as to have been kept up by the "turning out" system—the pine-tree-manuring it may be called—nor one on which the owner has used lime, shells, or any manure purchased or brought from abroad. Excluding then the most exhausting and bad cultivation, and also the most improving and profitable, the remaining lands will show fairly the effects of the usual mode of tillage in this county—and in general, they appear to be such as will be now stated.

According to the system of tillage described, there is no such thing as any field having a year of rest: every acre (except the small amount of woodland reserved for timber and fuel, and the still smaller amount of land "turned out,") is under a crop once a year. Of course, *supposing products to continue equal*, there is twice the amount of cultivation, of amount of crop made, and of laboring and consuming population, as there would be if the land was at rest, and producing no crop two years in four. The people are in an uncommon and remarkable degree, (for Virginians, I grieve to say—) attached to the place of their nativity, and seldom think of emigrating to the far west, or even to the "Western Shore," (as they call all Virginia except their own narrow streak of land,) unless driven by the impossibility of obtaining a laborious support at home. It follows that the people are too many for the land, as it now produces, and the demand for land, both on purchase and rent, is as high as the profits of cultivation will permit—but not higher than that point, as is abundantly proved by the permanency of such prices, as well as by other circumstances. It may be safely asserted, that the average price of land in Northampton, is three times as high as that of the average of the lands in Prince George and Surry, which border James River and extend back eight miles, and for nearly all of which, marl might be used with sufficient facility and profit—an immense benefit of which the Eastern Shore is deprived. In all that space, embracing some of the best and some of the poorest land in Virginia, though there are a few tracts which might sell for $30 the acre, the average price would hardly exceed $5—and many tracts containing marl, notwithstanding the increased demand and price for such land, would sell for $3. In Northampton, there is but little land (excluding the sea islands,) under $14, and much would now sell for more than $20—and the average price throughout would not be less than $15. It may however be objected, that such prices cannot be founded on correct estimates of profit, and therefore are no certain evidence of value. It would be very difficult to put down such an objection to high prices, if every man tilled his own land. But the best proof is offered here in the fact, that a considerable proportion of the soil is regularly tilled by tenants, and that there is demand for all offered to be rented out, at such shares of the crops as will pay six per cent. net, on the purchase, at the high existing rates. This is sufficient proof that the landlord can afford to buy and to retain land at the present prices. And if a tenant pays too high rent, he cannot fail to make the discovery by the time a year has passed. It may be safely assumed that annual rents, in general in every country, and especially in the United States, can never remain higher than tenants can afford to pay. Poor land is here rented, and cultivated in the ordinary rotation, at never less than one-third of the grain, and also of the smaller, yet important crops of castor bean and sweet potatoes. If of a little better quality, (and yet such as appeared to me quite poor,) it will pay two-fifths of the corn, and one-third of the oats and other smaller crops. Good land, say any yielding four barrels of corn, may be readily rented to tenants for one-half the crops made. The landlord keeps the buildings in repair, and the tenant the fences. For land of apparently equal productiveness in Prince George, not half the same nominal rent can be obtained—nor can lands be rented out at all, as a regular and continuing system, to any who will so cultivate and manage them, as not to injure their value nearly as much as the amount of rent is worth. From all that has been heard on this subject, I cannot but believe that the lands of Northampton are well worth their present prices, under their present management: and, if from so slight a glance I may presume to offer the opinion, it seems equally clear, that by retaining what is really excellent in their system, avoiding some very general errors, and adopting means for additional improvement, which are quite available and yet almost totally neglected, that the same exercise of industry and economy so directed, would advance the net profits, and of course the prices of land, to the double of the present estimates.

It is admitted that there are reasons why the Northampton lands should be worth more in proportion to their average and continued returns to the acre, than most other lands. Such reasons are presented in the almost entire absence of all waste and worthless spots, whether in ravines or hill-sides, or for want of drainage—great ease of tillage, caused by the soil being level, dry, and light, and by its being kept always clean by annual cropping. But though these are important causes of value, they are not greater than the different advantages which other lands west of the Chesapeake possess, and which, notwithstanding, are at prices very far inferior. The cheapness and profit of marling on many poor soils, and their after fitness for wheat and clover husbandry, and the natural fertility of the best soils, seem to be at least a fair compensation for the want of other advantages peculiar to the Eastern Shore. If then the latter lands are held at fair prices, as there seems no ground to doubt, the good or improvable lands west of the bay are just as much below fair prices, as they are below the usual prices in Northampton. Why this remarkable difference should exist, is an interesting subject for inquiry, and the results would serve to throw much light on the causes of the general decline and low state of the prices and profits of landed property in Virginia. From the slight view which I have been able to take, it appears that the principal cause of the remarkable difference in the prices of lands on the Eastern Shore and in the balance of lower Virginia, is found in the difference of the modes of thinking and acting as to continued residence, and emigration. It may be said truly that the people of the Eastern Shore only, of all the inhabitants of Virginia, as a community, feel that they are *at home*—that they and their children are to live and die where they were born, and have to make the best of their situation. Compared with this state of things, the population of the balance of Virginia may be considered as in a state of *transition*—having future migration in prospect, either for themselves or for their children. If only one-third of the community are operated on directly by such considerations, they are enough to bring all the lands of the country to the prices and condition of their own. With so much land always offered for sale, and at almost any sacrifice, the prices of all must necessarily and continually decline. The formerly contented and industrious and successful improver of his farm, finds that it has sunk in price more than his expense incurred for its improvement—and that he might have bought at a lower price the lands about to be deserted by his neighbors. Hence grows discouragement to all permanent and valuable improvements—general and increasing discontent with their homes—and next the willingness, and finally the expectation, of following to the west the more enterprising, or more greedy, who had gone before them. The long continued prevalence of such opinions and habits are alone enough to ruin any country: and the mere absence of this curse seems enough to maintain the superior thrift and prosperity of the county of Northampton. The opposite conditions of the two communities may be compared to the different operations of the institution of marriage when indissoluble except by death, and where the law offers and invites divorce at will. In the former state, the parties are compelled to make the best of their union, and in the latter they would as certainly make the worst of it.

From what I could gather of the opinions of farmers of this county, it was inferred that the land was naturally, as it still appears, of middle quality as to productiveness. I heard of no farm, or even a field, which was supposed by its owner as having in its best and original state, to have produced more than 30 bushels of corn to the acre—which is certainly a very moderate crop on land peculiarly adapted to that grain. Probably in some places near the creeks, there were spots of much greater natural fertility: but all such could not have amounted to any great extent. I saw no land, other than the highly manured lots about dwellings, which now would produce 30 bushels; and not much which by its present growth promised more than 20 bushels of corn. Still I may be deceived in this respect, not only for lack of judgement, but because the grain may be greater in proportion to the general bulk of the plants, than on other soils. This is asserted of their oat crops, which appeared to my eye generally meagre, and very few spots were seen where the growth was very luxuriant. Yet it is affirmed that their ordinary round stacks will yield not much short of 200 bushels—and if of wheat, and elsewhere, they would hardly exceed 50 bushels.

The land was formerly covered with a heavy growth of excellent timber—oaks of different kinds, hickory, &c. as well as of pine. But almost nothing is now left but pines, and those of late growth, and of course very worthless both for fuel and timber. This remaining cover of the land not brought under cultivation, gives it an appearance of having possessed but little fertility, as we involuntarily associate an unmixed growth of pines with the idea of worn out land, or a bad natural soil. But though such growth is probably found here on better soil than it would indicate elsewhere, the general if not universal disposition of this land to throw up pines is enough to prove that it is no where *calcareous*, and that it is much wanting in that essential quality of soil. On the other hand, the rare occurrence of land naturally very poor, and the general and remarkable durability of all, would seem to forbid the conclusion that much of the soil was of such acid quality as lands favorable to pines generally possess. There can however be no doubt but that an addition of calcareous earth is every where wanting, and on every field would give increased productiveness and value. Very little use has been yet made of this all-important means for improvement. There are no beds of fossil shells, or rather they here dip too deep to be reached by any digging yet tried—and some few wells have been sunk to the depth of 40 feet. These beds disappear on the Eastern Shore of Maryland, by sinking gradually as we approach the south, (as stated in Dr. Ducatel's geological report,) and it may be supposed that they underlie the counties of Accomac and Northampton, though at a still increasing depth. But though thus deprived of easy access to this the most cheap and valuable form of calcareous manure, the quantity of shell fish would furnish lime in abundance—and there are many oyster shoals, naked at low tide, where immense quantities of shelly matter might be cheaply obtained. This if crushed would be better than if burned, as there is much putrescent matter which is destroyed by fire. The little use which has been made of quicklime (not extending beyond a few experiments) has not produced results which encouraged the repetition—and hence has arisen the opinion that prevails unfavorable to the application of calcareous matter in general. My observations did not reach farther north than about the middle of the county—but I heard that some gentlemen nearer to Accomac still persevered in using lime. It is not at all surprising that quick or caustic lime should be even hurtful to these lands, however much they may need mild calcareous earth. From the dry and sandy nature of the soil, and the continued tillage to which it is subjected, there can never long remain any inert or insoluble vegetable matter; and on all the vegetable matter in the soil, fit to feed plants, or rapidly becoming so, the caustic and burning action of quicklime is decidedly injurious, by decomposing and dissipating such matters. Thus the early destructive power of the lime, applied in its quick state, has here apparently overbalanced the more slow and permanent benefits which it afterwards produces as mild calcareous earth. This is one of the numerous cases in which a want of the knowledge of the mode of operation, causes even facts to lead to false conclusions, instead of teaching truth, as they would do, if properly understood. It is of great importance to this country that a proper estimate should be made of the value of calcareous and marine alimentary manures, as there are great facilities for obtaining both, as well as great need of them on most of the soils.

Next to corn and oats the castor bean, and sweet potatoes are the most important articles of culture in Northampton. There are seven oil presses in and near the little village of Eastville, and perhaps more than twice as many in the whole county. New ones are now erecting. One is to be worked by steam, for which the machinery is provided, and the necessary fixtures are now constructing. This seems a singular, and I fear will prove an unprofitable application of steam power. The oil cake, or "bean pomace" as it is called, is highly valuable as a rich and sure manure. It sells readily at 25 cents the bushel at the oil factories. Its effects are very great, as may be inferred from the price, but they seldom last beyond one crop, unless heavily and wastefully applied.

There is much difference of opinion as to the value of castor bean as a crop, and its effects on the soil, even among those who have most experience of this new kind of culture. One practical and judicious farmer, who is considered very successful in his business, and who had formerly obtained unusually heavy products of castor bean, told me that he would not continue its culture for the highest price ever known. His principal objection was to its supposed exhausting quality. Others think it not more exhausting than corn—but it requires rich land, and cannot be continued on the same, without an immediate and considerable decline in product. But though a second crop of castor bean will not do well on the same land, if immediately succeeding the first, corn will produce as well, and some think better, than on the same land if not preceded by the bean. The management of this crop is very troublesome, when the time arrives to cut the ripened clusters. If not cut immediately, the outer coverings open and waste the seed—and indeed there is no avoiding great waste in this way. The clusters ripen successively, and ten or twelve times it is necessary to cut over the field, before frost stops the labor by preventing the later beans' maturing. Some persons, who do not consider the crop as particularly exhausting to the soil, are not satisfied that they have gained by this partial departure from their old and general rotation of corn and oats. The castor bean has not been made a part of any regular plan of rotation.

The crop of sweet potatoes is here an important object, not only on account of the soil being very favorable to the growth, but because of the facility for shipping the crop to the northern cities, where good prices are always sure.

The business of grazing live stock is very limited, both in extent and in profit. There are no standing pastures of arable land, and of course, the fields cannot be grazed until after the oats have been reaped and removed. Before that time, the cattle have very scant fare in the woods, and on the firmer marshes which border parts of the sea side. But few give any land to artificial grasses. The soil certainly cannot be naturally favorable to clover: yet it is said that fine lots of this grass are made by the few who give the manure and preparation necessary for the purpose. But it may be said in general, that so far as green food is considered, the cattle have a feast from the middle of July until frost, and a famine the balance of the year. Of course, dairy products in general are very poor. Those who have no marsh pasture, or other waste land fit for grazing, and who take good care of their stock, rely entirely on their grain and offal of the corn and oat crop, not only in winter and spring, but through half the summer.

In the foregoing statements of the general results of the system of culture here practiced, I have chosen to rely more on general concurrent opinion, than on particular facts; because of the great liability of a stranger to draw false inferences from the few facts to which his observations must necessarily be limited. Nevertheless, it may be useful to add some few of even partial and defective observations of facts, which maintain the general views already presented.

When first reaching the shore, it was not so much my object to seek for uncommon though valuable improvements in farming, and the use of means not generally used or accessible, as it was to learn what was the general practice, and the good and profitable practices which might be generally adopted. My inquiries to this end led me first to the farm of Mr. James Goffigon, who has cultivated with success and profit, for more than thirty years, a farm having no facilities for improvement, except what its soil yields. It is on, and eastward of the ridge, midway between the waters of the bay and the ocean, and not touching either. The tillage has been throughout on the regular corn and oat rotation, with grazing after the oat harvest. The horses, (when not at work,) and the few cattle necessary to be kept about the house, and the whole stock of hogs, are kept in a space of two or three acres, and are supported almost entirely on grain, and the dry offal of the previous year's crop, until after the oat harvest. The cattle which are not wanting are turned out in the spring, and go to the marsh land on the sea side. The whole stock, being kept at such disadvantage, is necessarily small, in comparison to the extent of arable land; and they live in great plenty on the pasture after the oat crop, and are unable to keep down, or destroy the succession of the general cover of the Magothy Bay bean. Much manure is made in this very long period of penning stock—is made necessarily, it may be said, when litter is given, as is done here, from the pine woods, as well as the offal of the crops. But Mr. G. does not speak favorably of the effects of his manure—and indeed the summer penning on fermenting litter, would seem likely to be wasteful of the fertilizing principles of the manure, and injurious to the health of the cattle. No other means of improvement, worth counting, have been used: yet the farm has not diminished in product materially, if at all, since Mr. G. has known it, and according to the report of others, is still one of the most productive in the county. But though the farm lies in part on the "ridge," and consists partly of the worst kind of soil in the county, the greater part was of the best natural soil in the interior. The field now in oats is the most distant from the homestead, and a large part of it has never received any aid from manure. Mr. G. supposed that this part would now make 20 bushels of corn, and in its original and most fertile state, might have brought 30 bushels. He rents out the greater part of his land, and the poorest, for two-fifths of the corn, and one-third of the oats, castor bean, and potatoes.

Mr. G. disclaims all pretensions to the character of a good farmer, and attributes all his success to steady attention to his business. He certainly has been an excellent manager of his means: and his undoubted and long continued success, taken in connexion with the total absence of all uncommon, or foreign means for improvement, and his continued adherence to the Eastern Shore rotation, serve to place in a strong point of view, the peculiar and durable good qualities of the soil, and the profit of the rotation in general.

The smaller farm of Mr. Isaac Smith, on the sea side, furnishes an example equally striking, of the ease and profit of increasing the products of an impoverished soil, by using proper means, and such means only as may be availed of by all. Mr. S. took possession of this farm in 1819. The product has been gradually increased, on the same surface, until it is now doubled. Being on the sea side, and having some firm salt marsh for pasture, he has rigidly secured his fields from being grazed at any time, and thus has regularly returned to the soil all of the improving crop of Magothy Bay bean, and secured its regular return as a thick cover of the fields. In addition to this, and to the use of the manure furnished by the stock and offal of the grain crops, Mr. S. formerly had the benefit of the pomace of castor beans, which he bought to make oil for sale. But that part of his business was never extensive, and he has for some years ceased to make any oil, except from his own crop of beans, raised on the same farm. The use of this manure was not properly understood when he at first might have profited by it, and indeed it was scarcely used at all, or thought to be worth using, except to remove an offensive nuisance. It was thrown out of the factories in bulks, and left to rot and waste—and was used as manure most injudiciously and to great loss. It is now saved under shelter, and applied in very small quantities. Mr. S. thinks that the whole amount of this manure which he used, that was not derived from his own fields, could not have exceeded 1500 bushels of the pomace properly applied. This I mention because it is the only foreign substance which has been used to restore the lost productiveness of the farm—and this is certainly more than counterbalanced by the oil which is every year produced on, and sold from the farm. It would seem then, that whatever Mr. S. has done to improve an exhausted farm, may be done any where, by the means furnished by the land itself, and under the corn and oat rotation, provided grazing is prohibited, and due attention paid to the preservation of manures.

Mr. S. thinks that cotton seed must contain at least as much of fertilizing matter, as an equal bulk of bean pomace—and probably much more, as the former have lost none of their oil, and the castor beans lose all that can possibly be expressed by the most powerful machinery. But the great difficulty with cotton seed, is to apply them as manure without destroying the oil which constitutes their value. Violent fermentation, to which they are commonly exposed, must produce a great chemical change, and particularly on so putrescent a substance as oil. The manure is still rich, but perhaps half its amount and value has been wasted. If applied before fermenting, the seeds sprout, and in the process of germination, the oil is certainly changed to a far less valuable substance. Mr. Smith has tried steaming his cotton seed—and this seems not only reasonable as a means of preserving their whole value as manure, but his experiment of the effect fully confirms the supposition. I saw where the steamed seed had been applied to corn, by throwing a single handful into each place where the corn was planted, and the growth was at least double in luxuriance and in promised product. This is a valuable improvement for other parts of the country where cotton is a large crop. Steaming of seed on a large scale might be done with very little trouble or expense, the object being merely to destroy the germinating power of the seed by heat.

The valuable farm of Mr. W. L. Eyre, exhibits a high state of improvement, and of productiveness that is rare in this county—and which he has principally produced himself, and within the few years which he has been in possession. The land, however, though much impoverished, was originally among the best, which of course gave the greater facility to profit, by the application of putrescent manures. Mr. E. has also abundant means to use calcareous and marine manures, and has availed of them to some extent, but not so much as might have been expected. It is unnecessary to speak more at length on this head, as I can refer to a communication from Mr. E., at page 731, Vol. I. of the Farmers' Register. The old oyster shoals which are there described, are found in various places on both sides of the county. They would not only supply calcareous manure, but other kinds in the salt, the mud, and the remains of putrescent vegetable, and animal matters. Another excellent use might be made of this as a material for compost heaps, in which should be placed in layers the fish which may be here caught in great abundance, and at little cost. The calcareous matter would receive, and preserve for use as manure, the products of animal decomposition, and by the chemical action prevent all waste: and it seems probable also, that by the action of the animal products on the shells, (as they certainly combine chemically,) that the shells would be made more friable, and easily reduced, when put on the land. Mr. Eyre now has fish in compost beds of earth and vegetable substances: but these substances are very inferior to calcareous matter for the purpose of absorbing and retaining the products of animal decomposition. When fish are applied directly and without preparation as manure, it is the most wasteful of all the modes in which they are used. If properly used, the abundance and cheapness of this material for manure would make it of immense value to many farmers in Northampton.

It has been already stated that the renting of land is extensively practiced in this county—and it is still more general in Accomac, where the more minute divisions of land, (for Virginia,) the comparative scarcity of slave labor, and other existing circumstances, offer interesting subjects for inquiry and remark, which it is highly desirable should be presented to the public, by some of those who have the means. Large land-holders may, if it is desired, derive their entire income, with ease and with sufficient profit, from tenants. Though the terms of rent are only from year to year, changes are not frequent. Mr. John Eyre, of Northampton, has long had a large proportion of his lands in both these counties, in the hands of tenants. He told me that he had never denied a continuation of the possession to but one person. One held the same farm for 35 years, paying half the product as rent, and in that time increased the landlord's share from less than 40 barrels of corn, to more than 100. He did this in part by new clearings, and by using the means for manure which the location offered, and which the landlord aided in, and though not in his obligation, to his own profit as well as his tenant's. Another of his farms was held 28 years by one tenant, who then died, and was succeeded in the possession by his son. Such cases would seem to show that there is more attachment to rented land on the Eastern Shore, than is felt on our side of the Chesapeake for freehold inheritances on which the owners were born, and on which perhaps several generations of their ancestors were buried.

My conclusions as to the soil and culture of Northampton, are very different from the opinions which prevail among most of those who are equally strangers to them. It is not uncommon to hear the country spoken of as but little better than a mere sand bank, and the tillage as miserable as the soil. These of course are exaggerated expressions, and would be so admitted by those who use them to express the contempt they really feel. It is possible that I may have erred as much on the other extreme. But my opinions are founded on reports of profits and prices, and of long continued products, and not upon the appearance of the land, or the growing crops, and still less upon any excellence of the implements or processes of tillage. The great merit seems to be, that though neither of these are such as would command admiration, or even attract notice, that all the parts are well suited to each other. If I had merely judged of the state of agriculture by what was presented to my view, and without knowing any thing else, I should have certainly formed a very unfavorable opinion of the soil, the rotation, and the profits and prospects of the cultivation.

A GLEANER.

July 17th, 1835.

USES AND CULTURE OF RUTA BAGA.

To the Editor of the Farmers' Register.

The Swedish turnip, or ruta baga, is a most valuable vegetable for all kinds of cattle. Some horses refuse it, but generally they are fond of it. When designed for horses, the roots should be well washed and chopped up—but for cows or hogs this is unnecessary. Indeed it is thought that cows thrive better upon the roots in their dirty state; and when given whole, they are not so likely to choke them. The teeth of sheep may be injured by roots in very dirty condition—but all these cattle eat more slowly and securely, I think, if the turnips are thrown to them in an undivided state. I used a turnip cutter when I first began to feed them, but discontinued it as troublesome and unnecessary.

The Swedish turnip, when first eaten by milch cows, gives the milk and butter a flavor something like that of garlic. This is not unpleasant to some persons, and becomes less obvious as the digestive organs of the cattle more perfectly assimilate the food. It may be obviated, however, by dissolving an ounce of saltpetre in a pint of water, and putting a table spoonful of the solution into each milk pan as the warm milk is emptied into it.

In the winter season, the butter from cows judiciously fed upon ruta baga, has the flavor and appearance of grass butter. Half a bushel per day, divided into three messes, is a fair allowance. I have sometimes fed a bushel and a half to each cow per diem. The vegetable is very grateful to the animal, which while eating it, requires little water to drink. I have known cows refuse to drink water for several weeks when freely fed on Swedish turnips. Straw, corn fodder, or coarse hay, is at the same time essential to enable them to chew the cud.

The skin remains slack, and the health more vigorous and decided, by the use of these turnips; and the amount of barn-yard manure is much increased. It is best to feed twice or thrice a day. In fattening cattle, Swedish turnips, sprinkled with corn meal, gives the meat a finer quality, juice and relish. It is also an economy where corn is high in price.

The ruta baga is generally thought to be a troublesome crop; and many relinquish its cultivation from the difficulty of its management, *when not thoroughly understood.* The ploughing or ridging, drilling, hand-hoeing, and care, are peculiar, and much unnecessary labor and pains often at first embarrass the cultivator. But when once well comprehended, the crop is usually estimated highly.

We generally plough up a barley, wheat, or rye stubble, immediately after harvest; then roll and harrow it well. If we have fine manure, (we often use street dirt and bones,) this is hauled out and spread, and the ridges (two furrows cast together) are ploughed at once. These are rolled flat, and the seed drilled upon the top of them with a machine (a turnip drill) contrived for the purpose; or a porter bottle with a quill fixed in the cork, having a hole of sufficient size in the small end of the quill. If the manure is long, and intractable, the ridges are ploughed first, the dung is then carted and spread between them, and the double furrows are afterwards split, so as to cover in completely the long manure. The seed is sown tolerably thick. When the plant has four leaves, the supernumeraries are cut out with hand-hoes, leaving the finest plants from six to twelve inches asunder. Eight inches is the average width between the plants—if they are allowed to stand thick, the crop is ruined, and no fear should be entertained to cut out freely.

Before hoeing, a light triangular harrow is run between the rows to level the earth, and clear the ground from weeds. An implement with a slide behind and hinges in the front, so that the width can be changed at pleasure, according to the growth, is most convenient.

A mistake is often made with the turnip crop, in *hilling up* the roots by plough or hoe. The earth, on the contrary, should always be taken from the turnip. Its tap root is quite sufficient for its nourishment, and the bulb grows larger as the earth is *drawn from* it. The calculation is to hoe and cultivate the ground until it is quite level, harrowing or horse-hoeing between the rows, and hand-hoeing between the growing turnips. We sometimes sow barley, wheat, or rye among the ruta baga for a permanent crop, and cover in the seed when we give the turnips the last dressing with the harrow or horse-hoe. I have seen very good crops of grain after the turnips, and 300 bushels of turnips per acre. In planting Swedes for seed, care should be had that no other plants of the same family be permitted to flower near them, or in the same garden. Other kinds of turnips, cabbage, and radishes, will change the character of the seed; and of course the quality of the roots will be subsequently altered from that of the original. A friend—G. H. Walker, of Hongford, Philadelphia County—who is exceedingly careful in all such matters, promises me to forward you some of the true breed, which you will do me a favor by distributing among our friends on James River, (especially to George E. Harrison and John A. Selden, his brother Miles D. Selden, and Hill Carter, Esqs.)

In your climate, except in very severe winters, like the last, you have the advantage of being able to leave the turnips in the field, to be pulled as they are wanted for use. Here we are obliged by the severity of the season, to pull and top them by the middle of November, and to hoard them away in cellars or caves, where they sometimes heat, and require much handling.

You can sow later than we do, for the plant is one of a cold climate, and grows rapidly after the first frosts. I am, however, now (June 30,) eating ruta baga raised this spring in my garden by mistake; the seed being sown instead of Savoy cabbage. I find them very palatable.

This turnip bears something the character of the pippin apple, which increases in sweetness and flavor by being kept. When the Swedish turnip is first taken from the ground in autumn, it has a raw, or rank taste, when prepared for the table; but towards the middle of winter, it improves very much. It is now sought after in our markets, often selling for 50 cents per bushel, for the use of the table, in mid-winter and spring.

Its color is a fine rich looking yellow when boiled, and the only objection I know to it is, that during the process of cooking, it gives out an unsavory odor. This is of less importance when the kitchens are separated from the dwelling house.

J. H. GIBBON.

Philadelphia County, 2nd July, 1835.

A REJOINDER TO MR. JOHN A. SELDEN'S DEFENCE OF THE NEW FOUR-FIELD SYSTEM.

To the Editor of the Farmers' Register.

Brandon, July 2d, 1835.

It was alike foreign from my intention and wish to appear again in the Farmers' Register on the subject of the new four-field system. Nor from this course would I now deviate, but for some remarks to be found in a communication from the pen of my worthy friend, Mr. John A. Selden of Westover, (which made its appearance in the regular number of the Register for the last month,) that seem to require some notice from me, however cursory, in justification of myself. At the same time I shall endeavor to show that some of the objections to this system are not altogether so trivial, and without foundation, as my friend would fain make appear in his elaborate defence of his favorite system. Still I cannot, and will not deny, that it possesses some great advantages; sufficiently great, perhaps, more than to counterbalance, in the opinions of many, the objections that may be fairly urged against it, allowing them their full weight. My confidence in my own opinions, on any subject, certainly has not increased as my life advances, and it is well known to me that some things succeed much better in practice than could be expected from an abstract consideration of all the arguments *pro* and *con*. Nor must it be forgotten, that this system comes strongly recommended to us by two of the most skilful cultivators of the soil in eastern Virginia, my friends of Shirley and Westover.

My friend Mr. S. says that I charged him with imprudence in recommending his system; and surely this is rather a hasty assumption, as any body may see (page 464, Vol. II. of the Register) by referring to the passage from which he infers the charge. I there state the difficulties to be overcome by each individual, in fixing on the best system; and then ask, if it is not imprudent to recommend any system for universal adoption? I then endeavor to show that no system can be suited to all situations and all soils; but that the rotation must be varied to suit the peculiar circumstances of each case. Now Mr. S. must have meant to recommend his system universally, or not; and as such was not his intention, the remark cannot apply to him; and if he had intended it (which he tells us he did not,) the truth of the remark must be evident to all. Besides, the proposition is general, and applies with equal force to all systems; and there is undeniably a great difference between this and the naked affirmation that Mr. S. had been guilty of imprudence. I even gave the example of Arator's four-field system, than which I know of no one more susceptible of profitable general adoption, to show that even that system will not answer in every case.

After commending the four-field system of Arator in deservedly high terms, Mr. S. descants on the frailty of human nature, which has prevented the more general adoption of it; and the passage in question might perhaps be misconstrued by one who did not know him, into a charge of unworthy motives against those who have had the temerity to disapprove of his favorite system. I am unwilling, however, to believe that such was his intention. When Mr. S. denounced in the strongest terms the disastrous three-field system (as he called it,) he surely must have expected that those who practice and approve that system, would say what they could in its favor. The wonder was not that I at length took up my pen in its defence, but that I had not long before been saved the trouble by some one of the many whose opinions coincide with mine, and who are so much better qualified to do justice to the subject.

My friend asks, if it is generous and consistent to adopt a system and then denounce it? Now I mentioned that I had adopted this system on a farm that had become foul under a lenient course of management, and that I did not expect to continue it longer than for a single round of crops. Surely the most scourging system might be resorted to for the purpose of cleansing foul land, and would, doubtless, be found the most efficacious. I said too, that I had a light field, exclusively devoted to corn, which furnishes a sufficient hoe crop; thereby removing an important objection to the system. If all this had been stated by Mr. S. his question would have been sufficiently answered without a single additional word from me. There are, however, other strong reasons why this system might answer on the farm in question, and not generally on lands bordering on the river. In the first place, this farm is better naturally, than the ordinary river land, though, perhaps, inferior to some favored spots; better for instance than an adjoining farm which I cultivate in three-fields. I believe too, that it is known to Mr. S. that I use lime quite extensively, by the means of which the crop of clover is ensured, and the land otherwise improved. Besides all this, the teams from the adjoining farm (cultivated in three-fields) aid in preparing the fallowed land, giving me a double force for that purpose. Surely these might be considered sufficient reasons, even for continuing this system here, when at the same time it might be thought too severe and too expensive for general adoption on the river. It must be recollected too, that my hostility to the system is not utterly uncompromising. On the contrary, I admitted that, under certain circumstances, I might myself pursue it. Allow me here to add, that I will endeavor to give this system a fair trial, and if it should fulfil any thing like the promise Mr. S. makes for it, shall certainly not be so blind-ed to my own interest, by pride of opinion, as not to persevere in it—or to the interest of others, as not to recommend it to them.

In arguing against the general adoption of this system, it must not be overlooked that so enlightened and so judicious a gentleman as Mr. John Wickham, on land too, of much better than ordinary quality, should, after having tried, condemn it. As much as his opinions are worth on all subjects, they seem to me to be at least doubled in value, when founded on experience.

Mr. S. thinks the number of horses or mules, necessary to cultivate a farm in three or four fields, equal; and states the number at 12 for 400 acres. This puts the subject in somewhat a tangible shape. In the latter part of his communication too, he gives the force employed in cultivating the Curle's estate in four fields, and states the number at 40 mules and 50 hands.

Now I leave it to all the gentlemen who practise the three-field system, to say, whether there is a single instance known to any one of them, in which, on a well managed farm under that system, the number of horses or mules is so great in proportion to the arable surface in the one case, or to the number of laborers in the other.

Perhaps I might be excused for having presumed on the authority of Mr. S. that a much larger number than 12 for 400 acres, is necessary under the new system; for in his first communication (in page 323 Vol. I. of the Register,) he tells us that he then worked at Westover, 11 horses, 14 hands, some inefficient ones among them, and but few oxen; and that these numbers should be nearly doubled to give a just exhibition of the four-field system. Now Westover contains 400 acres of arable land. Let me not, however, be understood as disapproving of an adequate team; but eight to a farm of 400 acres, under the three-field system, I should consider an ample allowance—more I am sure than are generally found on a farm of that extent.

It is difficult to imagine, when the proportion of horses and hands is as 40 to 50, that there will not be a good many of the former idle at many seasons of the year, when manual labor is required to be performed. Mr. S. says that under the three-field system, the horses are idle from the time the crop of corn is laid by till seed time; and elsewhere tells us that this is the critical time to plough under clover to improve the land, and also urges as an objection to the three-field system, that the corn land can very rarely be broken up in time. Now can any thing be imagined more easy than to give these idle animals employment by turning in a heavy growth of clover for corn; thereby avoiding all danger from the worm the ensuing spring, obviating at the same time, the objection to the three-field system, urged by Mr. S.; and by diminishing the labor to be performed the next winter, more time will then be afforded for collecting materials for manure. There are unquestionably some farms under this system, on which clover is grown to considerable extent without being depastured; and allow me to add, that the farm cultivated by me in three-fields, affords at this time ample evidence of the fact. There can be no reason why it should not succeed under this system on all land able to produce it; nor why it should be grazed off sooner than under any other system. If it were impracticable, or even difficult to succeed with the clover husbandry under the three-field course, I should be one of the first to abandon it; for I am endeavoring to improve my land extensively by the use of that valuable grass. Mr. S. says that the best clover does not grow on the best land. My best has certainly grown after lime and manure. Indeed, without the previous use of lime, the clover hardly pays me for the seeding; but in a few years we hope to have the whole arable surface here improved in that way, having already more than half accomplished it.

There is one argument in favor of the four-field system, which seems to have been overlooked by its advocates, and which it may not be amiss to advert to in this place. The scantiness of the second crop of wheat in the rotation is very favorable to clover, by sheltering the young plants without endangering their existence by suffocation, as is sometimes the case when the crop is heavy. In this point of view, I must acknowledge its decided superiority over the three-field system. If the crop of corn, succeeding wheat, made on a clover fallow, is as much benefited by the decayed grass, as Mr. S. contends, why would not wheat after corn, made on clover, (as under the three-field system) receive equal benefit?

Mr. S. labors to prove the superiority of wheat, as a crop, over corn. Whether he has succeeded, it must be for others to determine, and experience will be their best guide. It is certain that many of my notions are erroneous, and I am far from wishing that any opinion of mine should be practically adopted by a single individual, unless sanctioned and confirmed by his own experience and observation. With me, the crop of corn, estimating what is consumed at home at the price the remainder sells for, has been much the most profitable, and far more certain, however more variable the price may be. In the last two years, for instance, the gross crop of corn has been much the most valuable, although made on less land, after deducting $360 for *shorts*, each year. I will add that the quantity delivered this year exceeded the delivery of any previous year by 180 bbls. and that the moiety of it was sold from the farm under the abominable three-field system, although no more expense was incurred for shorts than for the last five years.

Admitting that as much corn can be made per acre under this, as under the three-field system, and that no more would be consumed, (and I am as far as ever from admitting either proposition—) as there would be one-fourth less land cultivated in corn, the gross crop would be diminished one-fourth, and as one-half of all made under the best management is usually consumed at home (even under the three-field system,) the quantity for sale would, of course, be reduced one-half.

On good corn lands that crop is not unfrequently the most profitable when shortest, (paradoxical as it may appear;) and the reverse of this is generally true with regard to the wheat crop. The reason is that the demand for the former is local, and the price is accordingly more affected by a partial failure.

Mr. S. rates his loss from shocking out his corn one year at nearly a sixth of the whole. Now we are in the habit of putting all our corn in shocks, in order to expedite the seeding of wheat, and a portion of it frequently remains out till January, and yet we have never sustained any considerable loss from the practice that I know of; and I can in no wise account for so great a loss, but by supposing some defect in the corn itself. When the corn is perfectly made, and not prematurely cut down, I am confident that my loss does not exceed two per cent. from exposure in the shocks.

We are told that land which will produce four barrels of corn, may be relied on to give twenty bushels of wheat on good clover fallow, well prepared, and seeded; and that 25 or 30 bushels may be expected under like circumstances, from such as will yield eight barrels per acre. In this part of the state, my opinion is that land that would bring four barrels of corn, will not generally, without the use of calcareous manures, bring good clover at all. It might be asked, too, if the land be equally well adapted to both crops, why the ratio of increase is not more nearly equal? I have always thought that there is no land, except perhaps pipe clay, to be found in this part of Virginia, that will yield as many bushels of wheat as of corn, which Mr. S's. first proposition assumes.

Under the four-field system there is only one-ninth more in cultivation than under the three, and admitting that the crops are equally heavy, (which is going far enough in all conscience,) there would be only one-ninth more offal to convert into manure. What becomes then of the superiority of the new system in this respect? For if there is one-ninth more manure made and applied, there is also one-ninth more land in cultivation, and that ninth is moreover deprived of the advantage of clover. I am willing to admit that the manure made from wheat straw is somewhat superior to that produced from the offal of corn.

The crop of corn made by Mr. S.'s predecessor at Westover, was but seven barrels per acre, though with very imperfect cultivation. Only a small part of the crop followed clover, as that gentleman informs me, and of course any calculation, based on the supposition that the whole had that advantage, can prove nothing.

Does Mr. S. regard as inconsiderable the expense incurred annually by wheat growers in seed? If I were at all happy at numbers, it would give me pleasure to calculate, as nearly as possible, the cost to the state of Virginia every year of this single article. It must be a pretty round sum, as one-tenth or more of all the wheat made in the state is reserved for the purpose; and from the noise made about the tythes in Great Britain, this would seem to be something considerable.

As I have crossed the Atlantic, I will now try to fortify the objection against the new system, derived from the universal practice of the best English farmers, which Mr. S. regards so lightly. He tells us that he does not read books on English agriculture, but knows there may be a great difference between the soil and climate there and here. This no one will deny, but I take it, the difference is decidedly against us, except that we can here cultivate that noble plant Indian corn, about the value of which Mr. S. and I seem to differ so widely. The climate there is very humid, and is accordingly admirably suited to grass, as well as small grain, which is partially protected from many casualties, to which it is liable here, by the coolness and equability of the temperature. In such a climate, one would suppose that severer culture might be admissible, than in a comparatively arid and variable one like ours. Allow me to advert, too, to the great abundance of lime and other manures, foreign and domestic, which are used there, and to the skill with which they are applied. Now if in such a country, with an overflowing population, where land is high and rents of course correspondingly so, labor is very low, and produce hardly ever fails to command a good price; three grain crops in succession are found to make too great a draught upon the fertility of the soil to be profitable; it would seem to follow *a fortiori* that they cannot answer here—where the reverse of all this is true. It is considered there an established rule, founded on long experience and profound observation, that the more rarely any crop occurs in a rotation, the heavier it will be found to be; and the reason is, that the specific food of the plants constituting the crop, will there be found in sufficient quantities in the soil to nourish them to perfection.

In answering this objection, my friend Mr. S. says that the corn crop, a summer and hoe crop, intervening between the two crops of wheat, prepares the earth with a pabulum the better suited to the last crop of wheat. I can very readily conceive that the corn crop will diminish the pabulum that the succeeding crop of wheat ought to find in the soil; but can in no way discover how it can add to the quantity, until the plants themselves revert to the earth in the shape of manure.

Mr. S. accuses me of inconsistency for approving the five-field system, and objecting to the new system, that it gives too little corn for sale. With regard to the farm on which I practised this system myself, I always had a sufficient corn crop; having a light field cultivated altogether in corn. We have, too, a large marsh, which answers for a standing pasture. As for my recommendation of it to others, it was only conditional, (as any body may see by referring to the passage,) viz: when the fallow system has already been determined upon; and I assigned as a reason why I should prefer it to the new system, that, as at least one-fifth of the farm would be required as a standing pasture, the same surface would be in cultivation, and the worst feature of the new system, the three successive grain crops, would be avoided. I never thought, and no where said that it was free from all the objections that may be urged against the new system. Indeed the fair inference from what I did say is, that I considered both systems liable to the same objections, with the very important exception above mentioned.

It is a little remarkable that Mr. S. in his account of the improvement at Woods' farm, (in page 324 Vol. I, of the Register,) where the crop was astonishingly increased, should inform us that this great improvement was effected without a standing pasture, and the cattle, of course, deriving their sustenance from the clover field, (as he expressly says,) and only one-fourth of the farm in clover; and should yet think it other than an improving system to have two-fifths in clover, with no greater disadvantage on the score of pasture land, and without the excessive draught upon the soil from three successive grain crops. In other words, Mr. S. would seem to think it better (other things being equal, for there is no standing pasture in either case,) to have one-fourth than two-fifths in clover, and three-fourths than three-fifths in cultivation, on the score of improvement.

The crops of wheat made by Mr. S. at Westover, have been certainly very flattering: but in accounting for them, he seems to me to overrate the merits of the system, and to underrate the natural fertility of his land, and his own excellent management, which would doubtless insure success under any system. As these crops have been produced as evidence of the excellence of the new system, it seems that the following remarks are certainly pertinent, and perhaps necessary to a proper understanding of the subject.

The crop of wheat made by Mr. S.'s predecessor at Westover, is by no means to be considered as a fair criterion of the productiveness of the land; for, as that gentleman informs me, it was all sown after the 10th of November, (the period assigned by Mr. S. and all other good farmers, as the proper one for finishing that operation in this climate,) by the force from another estate, where a full crop had been previously sown; and in addition to this, the season was extremely unpropitious for wheat—the crops in this neck being of such inferior quality, as to require a deduction from the price originally agreed on. Mr. S. is mistaken, too, (unintentionally I am perfectly sure,) in regard to the amount of that crop, which was larger than stated by Mr. S., and produced from less land; a portion of the former having been reserved, and removed elsewhere for seed, without the knowledge, it is presumed, of Mr. S.'s informant, and twenty acres of excellent land (as nearly as it could be estimated,) having been left out, in consequence of the advanced state of the season; it being then about the middle of December. These facts I have from Mr. S.'s predecessor.

As far back as 1816, 3100 bushels of wheat and 600 barrels of corn were made at Westover by my kinsman, Benjamin Harrison, Esq. of Berkley, after the estate had been long subjected to the most exhausting course. If I mistake not, and if I do I hope to be put right, Mr. S.'s own great crop of 3000 bushels from 100 acres, was made on land on which he had put little or no other improvement than clover and plaster, and what was obtained by a masterly preparation for the crop. By a reference to his exhibit of his crops, (see page 322 Vol. I, of the Register,) and to what follows, it will be seen that this field was never cultivated by him in corn till 1833; and as he tells us he applies nearly all his manure for corn, it is to be inferred, that this field at that time (1832) had received little or no manure. I wish if any one of your subscribers has the good fortune to cultivate as fine land in three fields, that he would furnish the data which Mr. S. complains so much that he wants. I cannot help thinking, if he is a good manager, that his exhibit will show more than 5 barrels of corn, and 12 bushels of wheat per acre.

I never for a moment supposed that Mr. S. was acquainted with the fact that Mr. Harding was the first to practise the new system, when he attributed the honor of having introduced it to Mr. James Selden. On the contrary, I am quite certain that Mr. James Selden adopted it himself, without any previous knowledge of the fact. Mr. S. says that Mr. H. kept at Dover as many as 50 or 60 cows, and derived a considerable part of his profits from stock: and if so, the exhausted condition in which he left the estate, is certainly not fairly chargeable upon the four-field system. Mr. S. says too, that Mr. H. improved very highly the farm to which he removed, and where he continued to practice that system till his death. I can only say in reply, that all his neighbors were not unanimous in regard to that improvement.

By way of illustrating the advantages of this system, my friend Mr. S. refers triumphantly to the result of the last year's cropping at Curle's. It is to be regretted that it had not suited his purpose equally well to give us the average sales from the estate, since it was purchased by the late Col. Wm. Allen, instead of referring to the results of the last year's crop, which greatly exceeded an average, and can of course prove nothing. If I mistake not, the crop of wheat of the last year exceeded, by at least a fourth or more, the average crop made on the estate since the purchase; and if so, (if I am wrong I hope to be corrected,) and if even then the crop was only 13 bushels per acre, as Mr. S. has informed us in the number of the Register for November last—this deduction of one-fourth, would, you perceive, reduce the average per acre to a very moderate one for uncommonly fine land.

It happens that an estate adjoining me was offered in even exchange for Curle's a few years ago, and the offer refused by Col. A. It would give me pleasure to present a comparative estimate of the crops made on this and that estate for the last, and several previous years; but I am prevented from doing so by the repugnance expressed by the proprietor, to such an obtrusion of his private concerns before the public.* Without entering into minute details, I will, however, take it upon myself to say, that the sales from this estate, for two out of the last three years, have exceeded the largest sum assigned by Mr. S. to Curle's, for the last very favorable year. It is proper to observe, that this estate has the aid of a small grist mill, and usually about $400 worth of wheat offal, but never more; but these advantages, it is believed, are more than counterbalanced by the pork raised and fattened on the estate, (none of which it appears is raised at Curle's,) by the support of a large and expensive establishment, and of a black population, the extent and inefficient character of which may be inferred from the fact of their being, at the last enumeration, 50 children under the working age. The despised corn crop of the last year, has, with the above aids, after supplying the heavy demands upon it, furnished a surplus for sale of more than 1500 barrels. On this estate, which is under an irregular but very improving course of cultivation, some fallowing is done, more than a fourth of the land is suffered to rest, and corn is largely aimed at as a sale crop. There are

*It is strange that any such statement as is here referred to, and which every reader would agree with our correspondent in deeming interesting and useful, should be considered as an "obtrusion of private concerns" on the public notice. If such was the view taken by all of those who are, or may be, contributors to this journal, it would soon lose its most valuable features. There would be presented no more authenticated facts and practical proofs—and the want of these could not be compensated by mere general and intangible statements and theoretical views, no matter how true, and though as ably maintained as so unsatisfactory a course would permit.—Ed. Farm. Reg.

more hands (I do not know that the physical force is greater,) and fewer horses than at Curle's, and great use is made of that valuable animal the ox.

Mr. S. says that from $1000 to $3000 worth of corn has been regularly sold from Curle's each year. Now when we consider the extent and fertility of that fine estate, and that all the pork used upon it is purchased, this is astonishingly little to be derived from that crop.

In conclusion I must say that, although on the very best lands, and with the very best management, the new system may answer very well, and I cannot doubt that it will; yet on ordinary land, with ordinary management, I am very far from thinking that it will ever be found to succeed. If I have not been misinformed, I believe that you, sir, have tried this system, and I am sure that many of your subscribers, myself among the number, will be both edified and gratified, if you will afford us the light, which you are so well qualified, by experience and otherwise, to throw upon the subject.*

I will now remark, that it has been my object to discuss this subject fairly and freely, but without saying a single word otherwise than respectful and kind; and I hope that my friend Mr. S. will receive what I have written in the same spirit of perfect kindness and good will, in which it emanates from me.

WM. B. HARRISON.

From the New York Farmer.

HOPS.

The opinions of intelligent and practical men, or rather the results of their own actual experiments, are of great value. This applies particularly to small farmers, whose operations, being on a limited scale, receive their immediate personal attention. In looking at such results, however; those who farm on a large scale are liable to be led into error in expecting that the same will follow an extended cultivation, forgetting that the success is in many cases mainly to be ascribed to this minute personal attention, stimulated and strengthened by self-interest. In extended concerns, that attention cannot always be given; and as much hired labor is employed, the powerful motives of interest do not operate. The large and enterprising farmer, therefore, must take this into consideration; as his concerns extend themselves, his risks are multiplied: and if the results of his cultivation are not proportionately correspondent to those of the small farmer, he must often place it to the account of circumstances absolutely beyond his control. Nothing valuable in this world is accomplished without perseverance, labor, fidelity, and attention. This is one of the wise provisions in the constitution of things; one of the benificent laws of a righteous Providence. On the other hand, labor, perseverance, fidelity, and attention, seldom fail, in ordinary circumstances, of reasonable success. The business of the farmer particularly demands his attention, and his ill fortune may be but too often traced to neglect, to this want of personal attention, to the division of his care among other pursuits, or to a miscalculation in extending his operations beyond his power of immediate and careful superintendence. These remarks often occur to me in my visits among our small farmers, with whom I have been much in the habit of familiar, agreeable, and instructive intercourse; whose affairs are managed under their own immediate and constant personal attention, and among whom I often meet, with the highest pleasure, with examples in a small way of eminent success. I have been long accustomed to note the observations of such men, and to gather and record any facts which they have been kind enough to communicate, where I knew I could rely upon the correctness of their statements. I now send you some information, obtained in this way, in relation to the cultivation of hops by two farmers, who cultivate a small farm in partnership, in a town in Vermont, on the Connecticut river.

Messrs. D. & H., in 1833, from four acres obtained 3000 pounds, which sold for 20 cents per pound. In 1834, from five and one-half acres they obtained 4000 pounds, which sold for 15 cents per pound. In 1833 they judged that their land, after deducting all expenses, yielded an income of $100 per acre.

Hops are planted eight feet apart in hills. The cuttings are planted, and Indian corn is cultivated among them the first year, about half as thick as when planted by itself. The corn and hops are hoed at the same time. The second year the hops are polled and a crop gathered.

Green barn manure is thought to be injurious to the vines. Fall manure, or compost, is deemed best. The hills are opened in the spring; the vines are then trimmed, the ground loosened, and the manure applied to the hill. The field must be kept clean of weeds. The hops are gathered by hand. Women are employed in the picking at 20 cents per day. They require to be kiln-dried immediately, as they are very liable to be injured by heating in the heap. From 45 to 75 lbs. are kiln-dried at a time, and the process of drying occupies about 12 hours. After drying they are put into a heap and suffered to sweat a little, and then conveyed to be packed and bagged, which is done by a screw press. They are packed and screwed for about $5 per ton, and are then sent to market without delay. The manner and condition in which they are put up is of the greatest importance, for if the inspector discovers, on trying the bag, the whole bag is condemned. Spruce poles for hops, about 15 feet high, cost here one cent apiece. Messrs. D. & H. gave 25 cents per one

---

*Our personal experience of the new four-shift system is so limited, and the all important part of it, the fallow process, has been so imperfectly executed, that our practice would be worse than worthless, as affording an example for imitation. But they who have committed the greatest errors may be at least trusted to point them out for the avoidance of others—and in that manner only can the results of our experience be of any value. But as imperfect as may be our views on this interesting subject, as they have been called for, they shall be presented at some early time—upon the ground that we hold every reader of, and contributor to this journal to be bound to answer, so far as may be in his power, such inquiries as may be addressed to him by any other reader and contributor.—Ed. Farm. Reg.

hundred and cut them for themselves. They will set this year about 4400.

The market price of hops is very fluctuating, and the risk of curing them well is very considerable, and requires great experience and care. The ordinary yield per acre I am not able to state, as it varies greatly. In some parts of this state they are extensively cultivated; and on land, which, without great attention, would make very small returns. A farmer in Boxborough, Mass., recently from five acres of land gathered 10,000 pounds; and I have been credibly informed that a farmer on the river, about 12 miles above this, the year before the last, received from twelve to fourteen hundred dollars from the sale of his crop of hops. The cultivation, I am persuaded, might be extended to great advantage, as there is little fear that the market will be over supplied. It must not be forgotten, however, that the quality and condition of the article, when sent to market, is of the first importance. Good hops will always command a fair price. Damaged or ill-conditioned hops are worthless.

PEACH TREES.

Mr. William Phillips, of Pennsylvania, has derived great benefit from the application of air slacked, old effete lime to peach trees, the effects of which, according to his own account, have been very great. He puts about a peck of lime to each tree; he thinks it useful as a preservative against the insect so fatal to these trees. We have then two applications recommended, unleached ashes and lime, and from our own experience are able to recommend both. We are not sure which has the preference. The lime and ashes should both be dug up every spring. A friend suggests that he killed his young peach trees by lime; caution is needed in the application.

GENERAL OBSERVATIONS ON THE OLIVE, ORANGE AND DATE TREES GROWING IN GEORGIA—RUTA BAGA TURNIP AS A SECOND CROP AFTER CORN.

St. Simon's, (Georgia,) June 17, 1835.

I am unable to excuse myself for not sooner replying to your esteemed letter of the 15th of January. I did intend writing you something on such matters, as had come under my observation, particularly respecting the olive, orange, and dates. The frost of February has destroyed those trees, leaving nothing but stumps and wrecks behind. I shall, however, still make some observations:—

I had a very pretty grove of 200 olives, imported about 10 years since, their stems from 8 to 12 inches diameter, and, perhaps, averaging 20 to 25 feet high to the top; they have borne fruit for some years. I had also near 600 trees, or plants, from 11 to 5 years old. From comparisons between the olive and orange, in previous severe frosts, where the orange was much hurt, the olive was uninjured. I have, therefore, no hesitation in believing the olive is well adapted to, and will succeed on our sea-coast, of both Carolina and Georgia.

I have been personally acquainted with sour-orange trees, both on St. Simon's and Jekyl, for 58 years, and believe they were planted near 100 years since; and have never been killed by frost until last February. when they were all destroyed. I therefore, conclude, that since the first settlement of Georgia, the olive would have succeeded. It occurs to me, that notwithstanding the present immense value of the olive in France, they have been cut down in some severe frosts.

The olive and orange seemed so completely destroyed, even to some depth under ground, that I cut them down, and planted corn in their place; on examination about a month since, the lower roots still appeared fresh, I concluded that opening the ground around them might encourage vegetation; and have now the satisfaction to see the olives pushing out abundance of fine strong shoots, not one failing. The oranges are doing the same, though some appear dead, not yet decided; by returning the earth to the olive shoots, they will throw out roots, and furnish fine plants. In fact, I am better satisfied respecting the success of the olive than I was before the severe frost.

I had little hopes of any date trees surviving—some appear certainly gone, others are sprouting from the roots, some from the tops; a few put out blossoms—so I close the list of my misfortunes in that way.

I like to have some hobby in the agricultural line—my present is, raising ruta baga, a double crop after corn. In prudence I should wait another year's experience, but as the season advances, I shall relate what I do know. Every horticulturist in the southern states must have his mortification, after preparing land, to find his seed bad; indeed, he is quite an honest seedsman, that only mixes three-fourths of bad, to one of good seed. I have seldom ever been so fortunate. Accident threw in my way an advertisement of *William Cobbett, No.* 11, *Boltcourt, Fleet-Street, London*, offering warranted seeds for sale, of his own raising, particularly ruta baga seed, warranted, at the following rates, if 25wt. price 9d. str. per pound, if 50wt. 8d., if 100wt. 6d. I got some of his seeds last year, all good: and have some arrived this year. These particulars I mention for the benefit of those who may attempt the culture of turnips or other articles.

Mr. Cobbett sends his seeds to any place (cash first paid;) mine were sent to Liverpool, expense trifling, and there put up in an air-tight tin canister, sufficient to hold half barrel of flour, expense 5s. 11d. But to the turnips.

My corn, as usual, in rows five feet apart, land well ploughed in the spring by oxen, and entirely attended during summer by a small cultivator harrow of three teeth, and a light mule—no bed to the corn. In all August and September, say to the 15th of September, I consider the season in our sea-islands—the corn was stript of their leaves, and tops cut, a furrow was drawn between the rows with a shovel plough, and two bushel baskets of manure, dropt into each task row; a furrow on each side with a bar-share, covered the manure, and made a small bed; the top being levelled with a hoe, draw a small trench, two inches wide, one deep, and therein, at every 10 inches, drop five or six seeds.

Such particular and good directions are given in William Cobbett's Year in America, also inserted in the Baltimore American Farmer, 1st volume, that I refer to it; as soon as convenient pull up the corn-stalks, and throw the earth on each side to the turnip bed; the rows will of course be five feet apart, but where land is plenty, this is an advantage. If there was no corn I should not plant ruta baga at a less distance than four feet. The following spring plant corn in the turnip bed; it will receive the benefit of the manure. I am convinced land this way will be much improved and produce double crops; the last crop (turnips) more valuable than the corn.

I planted eight acres this way last year; the season was dry, and my people awkward: the seed though good, came up badly, from drought and bad planting; my ruta baga being exhausted I filled up with Norfolk turnip; crop hardly set till late in September. Turnips, as Cobbett says, are poor watery things, compared with ruta baga, and so they are; yet, quite beneficial to cattle fed on dry food. Most of my field consisted of Norfolk turnip, and I commenced on them, reserving the ruta baga till the last, having many oxen; I regularly fed, during December and January, 30 bushels of turnips per day, chopped up raw, and found much advantage.

My allowance of ruta baga, was five bushels per day, which was boiled, for experiment. I fed two horses one month thereon, without grain, only rice-straw; I never saw horses thrive better. Some sheep were fed on boiled ruta baga, raw Norfolk turnip and cotton seed; I never saw fatter mutton. Poultry requires no better food. My negroes had free access to the turnip patch. I preferred the ruta baga; seldom eating a meal without a plenty. When the frost happened in February, the Norfolk turnip was entirely destroyed, and though the ruta baga were frozen, after being thawed, they remained good. My present crop of corn, planted in the last year's turnip beds, looks very well.

I am respectfully, dear sir,

Your most obedient servant,

JOHN COUPER.

From the Southern Agriculturist

OBSERVATIONS ON THE STINK-WEED, (CASSIA OCCIDENTALIS) RECENTLY TERMED THE FLORIDA COFFEE.

St. Helena, June 15, 1835.

Dear Sir—In the last number of the *Southern Agriculturist*, I see a short article upon the Florida coffee. The writer is perfectly correct in saying that it is nothing more than a useless weed, which grows here abundantly, but he has mistaken the name, supposing him to have purchased the same kind of seed that I did. He calls it the horse indigo, *(Babtisia tinctoria,)* the *Sophora tinctoria* of Linnæus. This plant is delineated in Prof. Rafinesque's Medical Flora. The plant which I have hatched on the contrary, is the *Cassia occidentalis*, or Styptic-weed, or as it is very significantly termed in a note to the communication, stink-weed. It grows more abundantly in the town of Beaufort, than any other locality with which I am acquainted. It may be that Florida beats it in this respect, but if they can send all their seed elsewhere, they will be getting rid of a nuisance, and make a handsome profit into the bargain, if the seed maintains its original price. So great was its abundance in the vacant lots in the town of Beaufort, and so offensive its smell, that the inhabitants of that town, in the year 1817, when the bilious fever prevailed to an alarming and deadly extent, conceived the impression that the cause might be owing to this loathsome weed, or at least contributed to by it. They, therefore, had them cut up in all parts of the town, but unfortunately neglected removing them. The consequence was, that they became still more offensive. Since then, they have every year cut them down when working the streets, and "thrown them like the loathsome weed away." It is frequently used there as a styptic to fresh cuts, and I have been informed is considered useful for that purpose, but never having tried it myself, cannot say what its properties are in this respect.

I saw some of the prepared coffee in its powdered or ground state, and it had the appearance and the smell of coffee, but not its peculiar aroma. Indeed, there are a thousand things which when charred and ground, will deceive many persons. The rye thus prepared is used extensively in the northern states, in the interior, that with long sweetening (molasses) in contradistinction to short, (sugar) forms the principal morning beverage. In Germany, Chiccory is used either alone or combined with coffee, and this not at all confined to the poorer classes, but by many who consider it as giving an additional flavor to the coffee. So, also, in many parts, the roots of the Dandilion, (*Leontodon taraxacum*) is prepared and used in like manner. Indeed, as they are now applying India rubber to so many purposes, I would not be at all surprised if some one should advertise Caoutchouc coffee, as it has already been converted into bread, it can certainly be burnt into an imitation or substitute for coffee; and the same may be said of deal-boards, to all those who may choose to deal in such substitutes, when the *genu-ine* article, as our northern brethern can assure us, can be procured at a much cheaper rate.

Respectfully, yours,

CHARLES WM. CAPERS, M. D.

From the Southern Agriculturist.

IRRIGATION OF GARDENS.

"In the south of Spain, no garden is formed but in a situation where it can be irrigated; and the water for this purpose is drawn from deep wells by what is called a noria, viz., a kind of water wheel, which is described and figured in *Loudon's Encyc. of Agr.* The ground is laid out in small squares, separated by channels for conveying the water. Each square is a level panel, sunk a few inches below the water channel; and at one angle of each panel is a small opening in its bank or border for the admission of the water. On the margin of the squares, garlic is commonly planted. The olive is raised from truncheons of 8 feet to 10 feet in length, and from two inches to three inches in diameter. They are sunk about four feet or five feet into the ground; and the part of the truncheon above ground is covered, during the first summer, with a cone of earth or clay, to the height of from two feet to three feet, doubtless to prevent the sun from drying up the sap of the truncheon. Vines, in some places, are trained with single stems to the height of two feet or three feet, and then allowed to branch out like gooseberry bushes: they are manured with recent stable dung when it can be got, and the fruit is never found to be injured by it."—*Busby's Journal.*

Colonel Pinckney's house in Pendleton, is at the top of a hill, of about 70 feet elevation, and is at 800 feet, measured superficially, from a spring, which gushes out at the foot of the hill. The rivulet, or as we call it, springbranch, falls over one or two rocks at a little distance, but as the quantity of water is small, it is kept back by a little dam furnished with a floodgate self-acting, by means of a float, which lifts the gate as soon as a sufficient head of water is accumulated to act advantageously. The water falls upon a small wheel which sets in operation Hubbard's patent forcing pump; and the spring water is carried through leaden pipes, 18 inches under ground to the top of the hill, and is discharged in the kitchen; from which the surplus is conducted, by proper channels, from level to level, through the garden, on the hill side.

This example ought to be contageous, the only doubt of its utility lies in the use of leaden pipes; the proprietor considers the constant use of them as a sufficient security against the poisonous influence of the lead, but we know that lately objections have been made to the salubrity of the water conducted into the town of Mobile, through leaden pipes, notwithstanding their constant use; and the Messrs. Fabers, with several workmen, at their country seat, on Pon Pon river, have just recovered from very formidable and repeated spasmodic attacks, brought on by the use of water forced by one of these ingenious contrivances, through leaden pipes from their spring into their buildings. The use of wooden pipes or small iron castings would be free from any risk.

The precautions taken to supply abundant moisture to the cuttings of olive, show the cause of the failure to propagate the olive by cuttings in this country. In this city and at Mr. John Couper's, on St. Simon's Island, cuttings have been made to germinate, but after putting forth, the leaves perish and the cuttings become a dry stick under our sun. It is far easier for us to propagate the olive by seedlings, according to Mr. Mey's practice, described in the 6th vol. page 308, and confirmed in page 250, and in vol. 3, page 230 of the Southern Agriculturist—*Conductor of Southern Agriculturist.*

From the Ohio Farmer.

PROTECTION TO SHEEP.

Clarke Co., Ky. May 19, 1835.

It is known to those who have tried the experiment, that sheep put into the same enclosure with cattle that are in good order or cows having with them young calves, are completely protected by them, from the attacks of dogs; and I believe they would also be protected from the attacks of wolves, though of this last I have no experience, the wolves having been exterminated from this section long since.

These remarks are made in reference to the large breed of cattle we have in this county; but it is believed that any cattle that are tolerably fat, will show the same dislike to the dog.

S. D. MARTIN.

From the Petersburg Intelligencer.

MATOACA MANUFACTURING COMPANY.

We had the pleasure, a few days since, of visiting the works of this company, situated on the north bank of the Appomattox about four miles from Petersburg, and were no less gratified by the beauty and substantial appearance of the buildings than surprised at the expedition with which they have been erected. They consist of two cotton mills, three stories high, a machine shop and sizing house, built of granite of a superior quality, obtained from a quarry on the company's land. The principal mill is 118 feet long by 44 feet wide; the other 90 feet long by 40 feet wide. They will contain about 4000 spindles and 170 looms, a large portion of which have been set up and ready for use.

In addition to these buildings, the company have erected a granite house for a store, and fifteen or twenty frame tenements, as residences for the workmen, each to contain two families: and preparations have been made to erect as many more as the establishment may require. When the whole shall be completed, and the mills in full operation, it is estimated that Matoaca will contain between 400 and 500 inhabitants. It had already assumed the appearance of a village, and will, in a short time vie with any manufacturing establishment in the country for beauty of situation, the substantial construction of its buildings, and the care and attention bestowed on the comfortable accommodation of the workmen.

It is expected to put the works in operation early in the next month, and we understand that it is the intention of the company to manufacture all the cotton spun in their mills into cloth.

Matoaca furnishes another gratifying evidence of the enterprise of our fellow citizens, and of the increasing prosperity of Petersburg. We have now (in addition to the several well known flour mills) five cotton, and two cotton seed oil mills; and there remains a large unemployed water power on the Appomattox.

From the Farmer and Gardener.

IMPORTANT EXPERIMENT IN POTATO CUTTINGS.

Mr. Roberts—It being desirable among cultivators to produce early vegetables, I take the liberty of noticing through your journal, an experiment on the potato crop, which may possibly be found useful to your subscibers, and cause our markets to be supplied with new potatoes about two weeks earlier than is customary, besides enabling those who plant them to prevent the ragged and uneven appearance which potato crops too generally present when coming up. In order to have a full and satisfactory trial, I caused a large square of ground to be prepared in my garden, and laid it out in four long beds, all well manured. In one of these beds I planted the top or crown of the potatoes, (mercer) in the next, the sides, and in the two last, the crowns and sides promiscuously. The crowns are all up about eight inches high, and look very flourishing. On examining the bed in which the sides were planted I find them just sprouting, being but about one inch from the bulb, the surface of the ground having no appearance of vegetation whatever. The other two beds have come up as they were planted, promiscuously, presenting a very rough and uneven appearance, while some are eight inches high, others have not made their way through the earth. This patch was planted on the 18th June, and I mention the facts thus far developed, to encourage others to make more careful experiments, on more extensive scales, and to excite a spirit of inquiry: satisfied that we agriculturists have much to learn yet.

From the Farmer and Gardener.

ON THE MANAGEMENT OF ARTIFICIAL GRASSES.

Clairmont, 6*th Month* 20, 1835.

Edward P. Roberts,

Respected Friend—I have received thy letter of the 13th inst., containing 12 queries relative to the culture and suitableness of the most approved species of grasses, for dairy purposes, intended for the information of a gentleman to the south. And while I comply most cheerfully in replying thereto, I hope I shall be excused, at this busy season of the year, for making my answers as concise as possible. I am fully sensible that the subjects to which thou has called my attention, are vitally important, and are entitled to a more minute and extensive notice than I have leisure now to devote to them, but if a plain account of my opinions and practice, will be of any service to our southern subscriber and inquirer, or to others, they are at thy service.

1st Query. Is clover suited to being grazed by cattle, horses, &c.—or is it more profitable to cut it and soil the cattle with it?

In reply to this query, I may observe, that *red clover* is good for grazing cattle; but in order to derive the full benefit of enriching the land by it, the cattle ought not to graze on it until it is nearly or quite in bloom, whereby the droppings of the cattle, are in some degree covered by the clover, and the evaporation of the more valuable portions of the manure, thus to a considerable extent, prevented. The cattle should be taken off early enough in the fall to leave a good cover, to protect the roots of the clover, and prevent their being drawn out by the winter frosts. Clover is now generally known to be the best of all grasses for enriching and improving poor land; it should, therefore, be sown with all the varieties of spear grasses, viz:—orchard grass, timothy, tall meadow-oat, and herds grass, if the latter be sown on dry mellow land.

Although red clover is not the best grass for grazing cattle, yet it is essential to the grazing, as it fertilizes the land, and thereby promotes the growth of white clover and green grass, *poa pratensis*, which are considered as the richest and most acceptable to cattle of all grasses.

Soiling of cattle in the stalls have two good properties in it, viz. cattle thus fed furnish more manure, and require less land to provide the necessary supplies of provender, but these are not gained without additional expense, and great risk to the health of the cattle, which is certain to be impaired more or less, unless they are permitted to range abroad a part of each day.

2d Query. Is lucerne better suited to soiling milch cows than the common red clover; does it yield more green fodder, and is it earlier?

3d Query. Is orchard grass calculated to being grazed by cattle—does it sustain much loss from the treading down of the cattle while feeding?

Answer to the 2d and 3d queries. The cheapest and earliest article for soiling, is, I think, the tall meadow oat grass—*avena elatior*. The *lucerne* is equally early, and as good or better for soiling; but its culture is more difficult and expensive. The red clover soon follows them, and when ready to cut we have no occasion for a better article to soil with. The orchard grass and tall meadow oat, affords the most pasture of any of the spear grasses I am acquainted with, and will make good and suitable hay for cattle if sown thick, and cut when in flower, or rather before; continuing longer in sandy land than most other grasses and bears the trampling of cattle well.

I shall now answer the following of thy questions, under the same general head:

4th Query. Is it considered judicious to sow clover seed and orchard grass seed together to graze upon?

5th Query. Is it considered sound economy to sow the above grasses together for hay? In either case, what are the respective proportions of seed of each that should be sown to the acre?

6th Query. Will the orchard grass mature sufficiently early to be cut with the clover for hay.

7th Query. What quantity of orchard grass when sown alone, should be sown on an acre intended for hay?

8th Query. Should a larger quantity of orchard grass be sown on an acre intended for grazing than on one intended to be cut for hay?

9th Query. Will herds grass bear grazing; and is there much loss resulting from the hoofs of the cattle?

10th Which of all the artificial grasses within your knowledge would you prefer for grazing, and which for soiling?

11th Query. Which of the artificial grasses is the most profitable for hay, regard being had to its nutritious quality, facility of curing, and adaptation as food for cattle?

I am in the regular practice of sowing from five to six quarts of clover seed to the acre, in March, on land that was sowed in the previous fall with orchard grass, or tall meadow oat. They are in flower about the same time and are well calculated to support the clover, and be mowed together. The requisite quantity of orchard grass seed for an acre, depends much on how well it has been cleaned and prepared for sowing. I sow about two bushels when clean, first preparing it as follows:—lay the seed about four inches thick on a floor; make it thoroughly damp by repeatedly watering it well, and care should be taken to turn it frequently. It should remain thus for about 36 hours, which renders the seed heavier, causes it to fall freer from the hand, and enables the sower to distribute it more evenly, it not being from its increased specific gravity so liable to be affected by the wind. Another advantage gained is—it vegetates with much greater certainty.

Herds grass makes good hay for milch cows, being soft and nutritious, but the yield is not equal to other grasses, either for hay or pasture.—It may, however, be sown to profit on cold damp lands, where it thrives better than on dry land, and will grow on land too wet for any of the other grasses enumerated above.

I prefer clover and orchard grass mixed to feed cattle with in hay or pasture: and timothy and clover for horses. Although the clover ripens earlier than the timothy; yet if cut when in bloom, they make a better hay than either do separately. Owing to the astringent quality of the timothy, horses fed alone on it constantly, become costive, if not feverish, and sometimes both; these being the necessary consequences of such a condition of the bowels, when long continued. This injurious and natural tendency of the timothy, is corrected by the clover; its admixture therefore with the latter is absolutely necessary to the preservation of the health of horses. Should some of the clover when mowed with the timothy be so ripe as to crumble on making it into hay, it should not be considered as a loss; it falls to the ground where it decomposes, and in part repays the soil for what it has abstracted from it, and thus serves to fertilize it and enable it the better to nourish and bring forth its next crop.

12th Query. What quantity of seed of each of the several grasses should be sown—when—and how should the ground be prepared, manured, &c?

Answer to the 12th Query. In order to prepare lands in the best manner for grass seed, all the native grass and weeds must be completely eradicated by the culture of mellowing crops; such as Indian corn, tobacco, cotton or potatoes, or by a cleansing fallow of repeated ploughings and harrowings during the spring and summer; and if not rich enough to produce from five to six barrels, of five bushels each of corn, to the acre, manure the land and plough it in with a shallow furrow just before sowing the seed. If lime or ashes should be used, it will be best to harrow them in.

I prefer sowing the spear grass seeds in the latitude of Baltimore from the 1st to the 25th of September. However, on stiff clay they may be sown later, as also on sandy lands, owing to the injurious effects resulting from their heated surface. For every degree south of, and parallel with, Baltimore, and the sea-coast, sow the spear grass seeds about ten days later: and in the spring sow clover seed ten days earlier.

I sow about the same quantity of oat grass seed as of orchard, and about five quarts of timothy seed, and one-half a bushel of herds. It is the neatest way to sow the spear grasses by themselves: nor do they require, in my opinion, the protection of grain crops; but it is however, sometimes a convenience to sow these seeds on wheat, rye and oat fields—and often very judicious in a routine of crops. It is not, nevertheless, always best on grazing farms, the shattering grain frequently proving a weed to the succeeding grass crops, whilst those grain crops, themselves, substract much of the nutriment which should have been permitted to, and otherwise would, have sustained the grass.

Respectfully, thy friend,

ROBERT SINCLAIR.

From the Southern Agriculturist.

ON THE BENEFIT DERIVED FROM THE PEA CROP.

Woodlands, (Ala.) April 15, 1835.

Dear Sir—The great benefits derived from the pea crop in the south, are generally known to planters, but it will be readily granted by those acquainted with southern agriculture, that the advantages which a knowledge of this fact might give to them, are but partially experienced, owing to the want of being informed of a successful and ready mode of preserving that valuable plant. In No. 12, for December last, I think this subject is brought forward by one of your writers, and whose remarks has induced me, sir, to offer to you, and through your truly valuable periodical, the mite of my practical knowledge of the value of the pea, arising from the manner in which I cultivate and preserve it, and also apply it in the feeding and support of stock. And here, I beg leave to suggest an idea, the application of which I have frequently noticed, and not unfrequently felt, viz. that the relative value of any product of planting industry depends in a great degree on a judicious application of it, and a strict adherence to a well timed system of economy. Under a belief in the truth of this remark, I have appropriated my pea crop exclusively to the support of my milch cows and sheep, and fattening kids. It aids equally in the production of superior milk and butter during the winter, and fine mutton and lamb—four prominent items in comfortable living. The pea crop claims a considerable credit from the circumstance of being produced by the same labor that brings to maturity a crop of corn. Another value is fairly claimed by this plant, as an ameliorator of the soil, independent of a valuable product. The pea can be sown or planted after a crop of small grain is taken from the ground. My practice is to cut my rye and oats, what would be called early, or just before they are perfectly ripe, remove the grain from the field, and stack to cure, in some other, and turn in the stubble as soon as possible on peas previously sown—and this course more especially to improve my land, which last would be partially lost by cultivating the peas. This course is adopted also, not only to improve the land but to admit the pea to be put into the ground in good time to secure a heavy crop, and to give greater value to the straw of the oats or rye, and which I stack, or rather house, sometimes the day after cutting, by giving a liberal quantity of salt, sprinkling it over as I stack the last.

When I plant the pea with the corn crop, I put the seed into the ground uniformly, so as to secure one ploughing of the corn to the pea, as also a liberal share of the hoe. As early as the pea reaches maturity, anticipating about the time now admitted, in saving small grain, viz. "just before it is perfectly ripe," while yet the leaf and vine exhibit a growing state, the peas are pulled up, or cut at the ground, with knives made for the purpose of cutting down corn, the cutters returning along the row, cut by them, and gathering into small armsfull, raise up the bunch, placing it as upright as it can be made to stand, for the more free admittance of sun and air. If planted among corn, this last has been sometimes removed from the field, by being cut at the ground, saving in this way, stalks, blades, tops and corn. After one day's sun, I turn and raise up the bunches of vine and peas, and if any assurance of the continuance of good weather can be seen, I give them another day. The following I haul in, on a long coupled low-wheel wagon, fixed for the purpose with racks. Satisfied from reason and experience, that open pens are better calculated for the preservation of every kind of straw and vines in our climate, than close buildings, I have pens built of chestnut rails, about twelve feet in length, which pens can be removed at pleasure: in them I placed a tight floor of jointed plank, moveable if required, and raised about two feet from the ground. On this floor I lay a little well cured and dry wheat, rye, oats, or rice-straw, and on this, pea vines are put, until the layer, after being pressed down by the weight of a child, will be about twelve inches thick; on this layer salt is scattered—there is no loss by scattering the salt freely, the floor ultimately arresting what passes through in handling and feeding; what goes off with the pea vines being necessary for the thriving and health of the animals fed—the first going to salt my hogs the next year. The scattering of the salt is followed by straw, peas as before, and salt, until the pen is filled. when the roof of broad and sound clapboards is laid on, and secured by cross-rails, which interlock with the last put on.

In this mode of housing my pea crop, I consult saving time, convenience and economy. In place of a door, I have three of the rails so fixed on the front side, (or whatever one is most convenient to take out) that they can be moved as bars. The leaves and vines are generally taken out as green and sweet as when housed, and if possible, submitted to the cutting box, and which is found an excellent preparation for the use of the animal feeding on them. This last enables them to fill themselves much sooner. The vines are cut about an inch, and if not steamed, (which is a superior preparation for milch cows) are put into the feeding trough, and sprinkled with a liquid preparation of water, with as much corn or rye-meal in it as will produce the vinous fermentation, and used just as the *acetus* has commenced.

By pursuing this mode of saving, and using this plant, it will readily occur that an acre gives, when either planted among corn, or sown after grain, a fine quantity of dry winter food, and of a most nutritious character.

The period at which the vines are taken up, makes the pod hold the pea much more tenaciously than if suffered to get perfectly ripe; consequently there is less waste in feeding. A few pigs suffered to run in the cattle or sheep pens, accounts honestly for every pea. If fed in racks, the peas may be fairly credited with the maintainance of one pig for every sheep, and four for each cow, during the time of feeding.

The straw is given out with the vines and eaten with avidity, evidently imbibing so much of the quality of the pea as to become very agreeable to the taste of animals, particularly oxen, to whom I give it frequently. In filling the pen, I place a large keg in the centre, drawing it up as I progress. This leaves an opening for the escape of any product of fermentation that may arise, as also, for the entrance of atmosperic air.

For a stock of that valuable animal, the sheep, there cannot be a superior winter provision, especially if a few turnips are added, or an hour in the day in a rye-field, with pointed attention to salting.

From a fair trial, I know this mode of feeding that animal, preserves a fine state of flesh, fleece and health, during our short winters. With some, kid is a delicacy, kept on this food along with the sheep, the real "savory meat" may be had.

CINCINNATUS.

KILNS FOR DRYING CORN—MODE OF INVESTIGATION IN THE CHEAT CONTROVERSY.

To the Editor of the Farmers' Register.

Granville, N. C. July 14, 1835.

I am desirous of erecting a kiln for the purpose of drying Indian corn to be ground into meal in the spring, and kept for use during the summer months. Will you be so good as to furnish through your Register, the most approved plan of building them? The size, the mode, and material of construction, &c.

The cheat controversy has escaped unsettled from your paper. If wheat is changed to cheat the fact may be demonstratively shown by carefully taking up by the roots the bunches of cheat, and washing the earth from the roots. If the hull of the parent grain of wheat can be found attached to the cheat, no one can longer doubt that the change does take place. I have in this way washed and examined often the roots of wheat and of cheat: the hull of the grain of wheat I generally found adhering to the roots of the wheat, but never to the cheat.

LUCERNE—MANURE ON BARREN SOILS.

Lynchburg, July 9th, 1835.

This valuable grass is not sufficiently known among our farmers. I have had a lot of it for several years, and am much pleased with it. Although it is not calculated to supercede clover on a large scale, and one cutting does not produce quite as much, yet it has several advantages. It is fit for use twelve or fifteen days earlier—can be cut from four to six times a year—never salivates, but is good throughout the season, and does not require renewing for many years. Every farmer should have, at least, a sufficient lot of it, but as it requires free manuring, it will, as a *crop* suit only those who have much manure and little land. And here permit me to make a few suggestions respecting manure. Every well directed movement that is made in relation to this article gives the most ample returns, but like all other operations, it requires judgement. Rich stable manure ought to remain *under a shelter* till carried to the field. Only observe the large quantity of highly colored water it gives out after a heavy rain. When there is plenty of straw, corn stalks and other litter, the case is different, as these absorb what would otherwise run off. Indeed it is probable that a large portion of the value of the corn stalk as a manure, is owing to its capacity for absorption. In general, land that is "*born poor*" cannot be manured to advantage, until something is done to change its *constitution*, whether it be lime, marl, burnt clay, ashes or other substances. We all know that the decomposition of vegetable matter tends to improve the generality of soils: yet there is land in our country that has had weeds, grass, leaves and other matter rotting on it for hundreds, and perhaps thousands of years, and is yet poor. There are lands in the neighborhood of large cities which the skill of the chemist and farmer combined, has not been able to render fertile. I am informed there is land not many miles from London itself, that has never been made productive. It would certainly be a waste of manure to put it on such stubborn soils. I am aware, Mr. Editor, that some of your readers understand these things much better than I do, but there are others who have paid little attention to the subject, and you know that to impart information, and correct bad habits of long standing in many persons, requires "precept on precept, and line upon line."

M. D.

EFFECT OF QUICKLIME ON THE MAGGOTS OF HESSIAN FLY. CROPS OF WHEAT IN THE VALLEY.

To the Editor of the Farmers' Register.

Augusta County, Va., July 16, 1835.

You requested "a statement of some experiments and observations on Hessian fly." I have made no experiments on that subject, but suppose Mr. A. referred to some observations on that subject made by me when he was here sometime since. It consists in sowing lime on the wheat at the time it begins to shoot; the theory of the *modus operandi* is, that the egg that produces the worm, or small insect, is deposited through the blades of the wheat, and obtains vitality about the time the stem begins to shoot or rise up, and it begins then to eat it, or by its bulk prevent the growth of the stalk. The remedy is then to sow broadcast lime, first made as fine as possible and dry; and it must be sowed when there is a heavy dew, or during a shower of rain. About a bushel of lime to an acre is thought to be sufficient. I had last summer an opportunity of observing a piece of wheat that was treated in this manner. It appeared to become yellow and be on the decline; and after the application of the lime, it changed color and appeared recruited, and was at harvest almost as good as the other part of the field, in which there was not any fly. You can readily conceive the manner of the water or dew on the wheat becoming impregnated with lime, which it must receive in the process of sowing, and running down the stalk, and coming in contact with the young fly, and destroying it by its caustic qualities.

The apprehension of the most desponding is realized, as to the product of the crops of wheat in this region of country. It has been estimated at one-fourth of an ordinary crop. Perhaps taking Augusta County, it may turn out so—but in my neighborhood, I think, it will not be so much. I think that I will not have more than the seed sown, if so much—but some others will have half a crop, and some few as good as ordinary. Wheat does not ripen as it generally does—it is now the 16th of July, and I have harvested none as yet, though some people are cutting now. The time of commencing harvest here, is usually in the last of June or first of July. Wheat is generally thin on the ground, and we have had a late and cold spring, and wheat is taken with mildew, scab, smut, and almost every disease to which it is subject—and being so thin as not to cover the ground, weeds and cheat, and all kinds of trash grow up with the wheat. In Rockbridge, the county next up the Valley, the crops of wheat are much better than in this county: in many parts of that county I am told their crops of wheat are good—but down the Valley to the Potomac, I believe the crops have in a great measure failed.

WM. M. TATE.

For the Farmers' Register.

ON THE BAD EFFECTS OF COLD ON SOILS AND THEIR PRODUCTS.

Wardsfork, Charlotte.

In the first place, in those regions of the earth where winter is most severe, the soil is the most steril; and where warmth prevails, fertility abounds.

Secondly. Nature provides against the bad effects of frost, by covering the earth with trees, whose leaves dropping in autumn, prepare a covering against winter. Where cold is so severe as to benumb the vital principle of soil, there is nothing but barrenness.

Thirdly. Land newly cleared, is most productive (if well broke) the first year, being long secured from freezing by a bed of leaves. And those parts of the clearing produce best which have a southern exposure.

Fourthly. Land produces better after being covered during the winter by deep snows, as these snows prevent freezing.

Fifthly. Land is more productive where it is covered during the winter by logs, brush, stacks, and even rocks and clay, where there is no marl. Soils brought up from below the reach of frost, will also produce best.

Sixthly. Land broke in the fall and exposed to the winter freeze, does not produce so kindly as when broke in the spring: though the opposite notion is held by most, but it is neither agreeable to reason nor to nature. Uncovering the earth in the fall exposes it to all the disorganizing effects of wet and cold. Forwarding business, is the only thing that can be said in favor of fall ploughing.

Seventhly. The method which nature takes to restore exhausted soil, shows it is injured by cold. There is a *vis medicatrix* in inanimate, as well as animated nature. The way we are told to become eminent in medicine, is to watch the movement of the conservative principle; and so I judge it is in agriculture. When exhausted land is thrown out of cultivation, the conservative principle begins to prepare a covering for the soil. The broom-straw is generally selected. This humble sedge is only of negative advantage—nature only aims at a piece of economy—a home dress to hide nakedness and keep off cold, and tie the soil together, until she can prepare a better suit. The action of frost without this covering, would be altogether destructive. I have observed after a freeze succeeded by rains, the galls increase for want of broomstraw to hold the soil together, and there is a perpetual dividing and crumbling of particles of earth, and a vast quantity of this "real estate" is *really* hastening off to the sea. Such a "removal of the deposites" is producing waste and want in the land. It is for the want of nature's covering, that galls become gulleys—cultivation never made gulleys. Bad cultivation, to be sure, will assist; but good cultivation will not prevent the bad effects of freezing. Nature clearly shows that the mode of defence against this destructive agent, cold, is the covering of the surface. The next after the growth of sedge, is the old-field pine. Here nature aims at something more than a negative good: soil improves somewhat under this thick warm evergreen shelter, so secure against the action of frost. Nature surely abhors nakedness as much as she abhors a vacuum!

With some practical inferences, I shall conclude.

In the first place, I infer that the best mode of shielding the soil against the action of winter, is the great desideratum. Throwing your coarse manure over the surface, would contribute to this end. So would brush and other offal of your new-grounds. It also points out the great advantage of raising those grasses which would not only protect the soil against heat, but cold also.

Secondly. Galls and gulleys must be healed by covering them effectually against the action of frost, and diverting the rain waters from them by protectors. Never suffer any place naked of soil to be naked of clothing or covering. For cold in winter, is like old Harry Lee was in war: it makes for the weak points. It will be nibbling at such places through the whole winter, and they will be increased every year. What with the growing of *Yankee collections* and winter freezing, I think Old Virginia is dying not a very lingering death.

Thirdly. I infer that it is best to plough land in the spring; that plant beds should be covered during winter, and also garden spots; as keeping out the cold quickens the vegetating principle, and gives a forward growth to plants.

Fourthly. I infer that there is no necessity for the four-shift system, the grand promoter of emigration, sending off more than would an annual insurrection. If our fields were kept well covered with vegetation, and coarse litter, there would be no need of so much rest. The monopoly of landed property now increasing, and shoving out many of the laboring people to the west, is a serious matter to Virginia, and it arises in some measure from the idea, that it takes a longer time to make land rich, and it must be done by rest principally. If this notion remains with us long, the bone and sinew of the state will be driven off, and who will be left behind? A few of the genteel with their many *shifts* and many '*negers*' will have more high blood than high pluck, more bowels than brains; and will in less than a half century, (if they breed at all,) by marrying (but not loving) their rich cousins, fill the land with halt, withered and blind, which would take another pool of Siloam with an angel to trouble it, to make them whole again.

The view I have taken, suggests the necessity of covering the soil around the roots of grape vines, valuable shrubs, and fruit trees. Does not the close observer of nature see how she covers the roots of trees with leaves, full time enough to guard against winter? J. R.

From the Penny Magazine.

ON THE HATCHING OF POULTRY.

In the hatching of poultry, as in most other things, nature is the best guide. The hen and duck, if left to themselves, find some dry, warm, sandy hedge or bank, in which to deposite their eggs, forming their nests of leaves, moss, or dry grass. In this way the warmth is retained when the bird quits the nest for the moments she devotes to her scanty and hurried meal. The good housewife's mode is the reverse of this. She makes a nest, or box, of stone, brick, or wood, and fills it with clean long straw. By this means, less heat is generated by the hen, and that which is produced quickly escapes in her occasional absences;—the eggs are chilled and addled, and frequent failures ensue in the expected brood. To obviate this, the best mode is to put at the bottom and sides of the boxes of the henhouse, a sufficient quantity of fine, dry sand, or of coal or wood ashes, lining them with a little well-broken dry grass, or untwisted hay-bands, or moss, or bruised straw. Wood-ashes have been found to be the best, as they produce the effect of destroying the fleas by which poultry are so much infested; and that this will not be disagreeable to them is evident from the propensity which they have to roll in heaps of dust, or of ashes of any kind. An experienced rearer of poultry adopted the method above described during a long course of years and scarcely ever met with a disappointment.

From the Franklin Mercury.

A PROFITABLE CROP OF MULBERRY PLANTS.

A Northampton gentleman planted last year a half-paper (costing twenty-five cents) of the Morus Multicaulis, or Chinese Mulberry. The seed occupied a few feet square of his garden, and the plants came up to the number of about two hundred and forty. For these plants he has repeatedly this season been offered twenty-five cents each. The principal reason of this, however, is that the seed originally procured of this species of mulberry has all been consumed, and there is not much probability that any more good seed can be procured from the same quarter; and some years, of course, must be elapsed before it can be procured from the native trees. Other parcels of this seed have been obtained from China since the first was imported, but none of them have produced anything, having without doubt under the influence of the proverbial jealousy of the Chinese been subjected to some process, which, without affecting the appearance, destroyed the fructifying principle.

[The foregoing is a striking illustration of how many losses and disappointments will be sustained, before it is generally known that no reliance can be placed on the seeds of the Chinese mulberry for producing the same kind of plants. The several translated articles on this subject, which have been given in this journal, if regarded, would serve as very important instructions to those who seek to propagate this tree. If indeed it is true, (as alleged above) that the Chinese have destroyed the germinating power of the seeds before selling them, by the intended fraud they have rendered a service: as it is better to be disappointed by the seeds not sprouting, than in the kind of crop expected from them, after years have been devoted to the culture.]

From the Penny Magazine.

WILD DOGS IN VAN DIEMEN'S LAND.

The annoyance and danger occasioned by the wild-dogs in Van Diemen's Land is still a subject of great complaint in the papers of that colony; and the most active exertions hitherto used seem to have had little effect in abating the nuisance. The dogs appear rather to increase in number and boldness. A case is mentioned in which a person named Akerly was assaulted by thirteen of these animals, and would probably have been killed if he had not contrived to get up into a tree. The means hitherto employed to eradicate them do not seem to have been commensurate with the growth of the evil. A society has been established at Gaddesden, near Campbell Town, to effect their destruction; and the house of the chairman exhibits a collection of skins, to the number of a hundred, of dogs that have been killed, of almost all kinds, from the shepherd-dog to the Newfoundland. It is thought that unless the most decided measures are taken, it will be impossible to pasture sheep in the colony. The dogs bring forth six or eight young at a litter, and commence breeding at one year old, while the sheep brings forth only one, and does not commence breeding until two years of age. The ultimate and discouraging prospect which this opens is brought nearer by the daily defection of the domestic dogs of the colony to the wild ones. "At the remote stock-hunts," says a recent paper, "a free man keeps as many dogs as he pleases; frequently six or eight are kept; these dogs provide for themselves, and continually make off to the wild packs. All remonstrance is received with a smile of contempt, and returned by insult; and until such people are strictly prohibited from keeping dogs in the pastoral districts under heavy penalties, matters are not likely to mend: indeed it is to be feared that the evil is fixed for ever—that it has been too long neglected, and is now past remedy." We are too well assured of the resources and power of civilized men to partake of these apprehensions; but any delay now in organizing a plan of simultaneous operation against the dogs, is likely to render their future extirpation a matter of great and increasing difficulty and expense. Meanwhile, at this distance from the spot, it is interesting to watch the various aspects in which this remarkable state of things appears, and to observe the different measures which it may be necessary to adopt against the canine depredators. Since writing the above we find that an "Act of Council" has been issued for the purpose of restraining the increase of dogs. All dogs are to be registered; and none are to be left at large except in Hobart Town and Launceston. Unregistered dogs, or dogs found at large contrary to this order, are to be killed. The persons killing them are to be paid from 5s. to 40s. for each, out of a fund formed by the registration fees. The registration fee for a watch-dog kept chained, or a sheep dog, is 2s. 6d.; all other dogs 10s., or if females double the respective amounts. The local newspapers are not very sanguine in expectations of good from this measure.

EXTRACTS OF PRIVATE CORRESPONDENCE.

Abbeville, S. C., July 11th, 1835.

I congratulate you, sir, on the growing circulation of the Register. Yet it is a matter of surprise that a useful publication like this, which interests nine-tenths of the people, should not be still more eagerly sought for, and liberally sustained. Is agriculture, the first, noblest pursuit of man, unworthy of the investigation of the principles which constitute it a science, and of their proper application to practical purposes? This question will be promptly answered in the negative; still men, by their acts, seem to affirm otherwise. It is certain that one of the most efficient means of rendering service to the cultivators of the soil, is to present, in one view, the results of individual experience, by the examination and comparison of which, some principle may be deduced and established. And as the remoteness of individuals from each other preclude the practicability of a personal interchange of thoughts and opinions, such a work as the Register, may, through the facilities furnished by the press and post office, remove the barrier, and bring men who live many hundred miles apart together, without scarcely any trouble or expense. Its title to patronage is too obvious to demand labored reasons to prove it.

Columbia, S. C. July 12, 1835.

I had intended when I next wrote to you, to say how I was pleased to travel over again the farm of Lagrange in your last number. Our great and good friend Gen. Lafayette, and his son-in-law Mr. Delasterie, took me to see the whole of it, at which I was, of course, much gratified. I recognized most of the particulars as I read the account. The farm of Lagrange is, I believe, the best as to quality of land of that part of country; but some of his neighbors who have also their farms in the best order, deserve much more credit than they generally get; for, if I am not very much mistaken, they had to work on a most miserable flat, white and wet soil, and nothing but great skill and great industry could have made such farms as I saw there in a state of improvement.

Prince George, July 21, 1835.

I send you specimens of the *turkey*, and of the *blue stem wheat*; a couple of heads and some of the grains of each. They are both very fine. Examine them attentively, and see if you can discover any difference. They were raised but a short distance apart, a space of but 15 or 20 feet intervening; and bore so strong a resemblance throughout the whole period of their growth, as to leave on my mind but little doubt of their identity. If it be the same wheat, it may save some trouble to those who, or whose neighbors, cultivate it under the name of "blue stem," to be apprised of the fact. From the high reputation of the turkey wheat, they might incur some trouble and expense, too, to get that which they already have. I have been somewhat disappointed by finding that I have but one valuable variety, where I expected two. The blue stem has the character on the Pamunkey, where I derived my specimen, of being peculiarly adapted to low grounds, but is not otherwise considered a very productive kind. I understand it is exempt from the *strut*, as it is called in this neighborhood, to which the *purple straw* is unfortunately so liable.

While on the subject of wheat permit me to ask, through you, a description of the "*Washington white wheat*" of Maryland. Is it a bearded wheat, resembling at maturity, while standing in the field, the *golden chaff?* I received a barrel last fall, selected with some care, in Baltimore, under that name, which accords with the above description, but has turned out very indifferently, whence I infer that there may have been a mistake.

[The two samples of wheat seem, both in grain and head, to be precisely alike. Until receiving this sample of "blue stem," and finding it a white wheat, we had been deceived by that name, and supposed that it was meant for the "purple straw," of which the name is equally descriptive. Thus it frequently happens, from the confusion in agricultural nomenclature, that a term known to every body in one part of the country, is either unknown, or is applied to something else, at the distance of a hundred miles, or less.]

PROSPECT OF SEASON AND CROPS.

From all the information received, there is but little doubt left of a general loss in the wheat crop of Virginia, of between one-half and two-thirds. In Lower Virginia, we have heard of good crops no where, except in the neighborhood of Williamsburg—and all were not good even in that small space. The sufferers in such cases are apt to be persuaded that their losses are greater than afterwards may be found true—and besides, we have only statements limited to particular farms, or at most, particular regions of the state. But our reports all came from known and highly respectable correspondents, and are in every case made as correctly as the writers' lights have permitted. In this respect, they stand on a very different footing from the usual reports which appear in commercial newspapers, and which often are written by dealers and speculators, with the view of affecting prices for their private gain.

The crops of wheat in Pennsylvania are fine—and so it is lately said of New Jersey, and at least part of New York. The price in Virginia therefore cannot be as high as is generally supposed.

The corn in Lower Virginia now promises a good harvest. But much of its present luxuriance is owing to the recent frequent and abundant rains, which have produced a degree of succulence which will be the source of greater injury to the crop, should a severe drought occur in August. The uncertainty of the result, and the risk of diminished product is not lessened, but increased, by the present fine appearance of the growth.

July 29, 1835.

Lynchburg, July 9th, 1835.

A terrible tempest of wind, rain and hail passed over the centre of this place on the 27th of June, and in its range *totally destroyed* wheat, rye, oats, corn, and garden vegetables, and broke all the window glass which was exposed. Twenty-five birds, mostly doves, were found dead under one tree in a field near town. Much of the hail was solid, and large and heavy as hens' eggs; and several credible gentlemen say they saw stones big as a man's fist. It was something over a mile wide, and commenced in Botetourt, fifty miles or so west of this, and continued, I know not how far down. A similar storm, reported in the Enquirer, on the same day in Chesterfield, was probably a continuation of the same cloud.

Abbeville, S. C., 11th July, 1835.

The crops in this section of South Carolina, are more backward than it was ever known—and what I affirm of them here, may be justly predicated of them throughout the state. Our great staple, cotton, has been retarded in its growth by the lingering of winter in the bosom of spring. Planters commenced to commit their seed to the earth at the usual time in April, but the coldness of the soil produced by a winter of unparalleled rigor, and the hard chilling rains which succeeded the planting, destroyed the vegetative principle of many of the seeds, and caused, what is here termed, a "bad stand." These unpropitious circumstances, made the plants that did protrude through the crust of the ground, puny and sickly; thus rendering it almost indispensable to replant. The reward of the planter's toil now depends much upon the subsequent season, and the late arrival of frost in autumn. Indian corn, which is a more hardy plant, and can endure tribulations that would be death to its more tender neighbor, cotton, exhibits a more flattering prospect, except in such vicinities as have been visited by a drought of long continuance. But the rains begin now to descend in copious showers, and if they continue, corn crops will, no doubt, yield well. The oats are in general good, and have just been harvested. There was an almost total failure of the wheat crop. The intense cold of the winter killed it almost entirely, and some of that which did survive, was injured by the rust. The quantity raised will not near supply the demand for home consumption. Flour is now selling from nine to ten dollars the barrel. We must look to the north to supply the demand. Wheat with us has proved generally an uncertain crop—but I cannot avoid believing, that this is owing to a very defective preparation of the soil, and a want of attention to the selection of proper seed—though I will not venture to assert, that our southern climate is as congenial to its growth as a more northern one.

King George, July 13, 1835.

I am just finishing my harvest—the latest within the memory of our old men—and the most unprofitable. I do not think that I shall make more than one-third of an average crop. One-third of my crop was a clover fallow, the product of which will probably equal that of the balance, which was sown upon the best of the corn land. My estimate is, that the fallow will bring only four for one. The fly did me infinitely more mischief than the excessive cold of the winter. I observe that the wheat was better where the clover was plastered.

Frederick, Va., July 23rd, 1835.

Harvest is now over in this Valley pretty generally, and the reports of the newspapers to the contrary notwithstanding, I think the average crop of the Valley will not exceed one-fourth.

A CHAPTER ON DISCONTINUANCES OF SUBSCRIPTIONS.

If the Farmers' Register could live upon praises, it would be in a most thriving way—and there would be little ground to entertain fears for its decline, and final suppression, for want of a continued and sufficient support. If we were so disposed, we could fill many pages with unbought and unsought expressions of approbation from various subscribers and correspondents, and which however mistaken, or exaggerated, as testimonies of the value of this journal, were given (it may be presumed) as honestly as voluntarily, on the part of the writers. Very many of our correspondents know that passages of their communications of this kind have been either omitted entirely, thereby incurring some risk of offending our best friends, or the expressions of their favor and approbation have been softened and moderated in the publication, when they were so connected with the more important subject of the communication, that such passages could not be left out. This course has been taken, because such expressions of approbation, if published as received, would be considered more as evidences of editorial vanity, than merit—and would be confounded with the ordinary "puffs" which are so easy to procure, and the fabrication of which now forms a regular but disgraceful part of the trade of publication—and is a branch of the trade which is the most profitable to the least deserving.

But it is remarkable, (and would be not a little amusing to others less interested than ourselves—) that many of those who lavish praise on our work, at the same time announce the discontinuance of their support. Now we are well aware that kind feelings may often induce these disagreeable annunciations to be accompanied and softened by expressions of approbation—but we cannot therefore distrust the sincerity of the opinions so expressed, and which are altogether voluntary, and uncalled for. When any subscriber chooses to withdraw his support from a work, after having complied with all his obligation incurred on that account, there is no need of reasons or excuses being given for his discontinuance. Between him and the publisher, the transaction is a mere matter of business—an exchange of a certain amount of money, paid by the one, for certain services to be rendered by the other—and neither of the parties is under any obligation to the other, beyond the payment of the sum, or the service; nor to continue the bargain longer than it is desirable, or than a full equivalent is received for what is paid. If we expected more than this, we should be at least ashamed to acknowledge it. We only ask those who wish to withdraw their support, to do so in proper time. The whole year is open to them for that purpose, and when payment is made, and a discontinuance ordered for the end of the current volume, it will be as readily and as certainly entered early, as late. But many will subject the publisher to sending out one and even two or more monthly numbers of a new volume, before announcing an intention to stop at the end of the previous one: and in many cases, he is compelled to submit to this most unjustifiable imposition. The course of subscribers in such cases, is either civilly begging that a debt fairly incurred by them shall be remitted gratuitously by the creditor—or otherwise the debt is boldly denied, and the creditor must submit to the spoliation, for want of means for redress.

So far the matter is considered as between individuals—and so far, the editor pretends to have no claims on any subscriber's support—nor for any thing more than a bare compliance with obligations actually incurred. But there is another and more important point of view, to which attention is due. This applies to the general interest of the agricultural community, in the maintenance of the Farmers' Register, considered without regard to any particular or private interest, either of publisher or subscribers. Whatever may be the true degree of applause due to the operation of this journal—whether it be fixed according to the partial estimate of its warmest friends and zealous supporters, or of those who have never aided its efforts—or at any average degree between the opinions of friends and of *enemies*—it will certainly appear, that through this medium much service has been rendered to agricultural improvement and agricultural interests, even during its short course—and that such effects may be necessarily expected to continue to increase, with the age and increased influence of the work. If any persons deem the Farmers' Register to be worthless—or that its place would be better filled by any other agricultural publication—they are right to withhold their support. But among the great number who entertain opinions altogether opposed to these—who indeed would testify the most strongly in favor of its useful effects—it is strange that there should be so large a number who have never lent any support, or having done so, have withdrawn it. If only a tythe of the benefits anticipated from such a journal were to be realized to the agricultural community—and even admitting that an individual should derive from it no special and private benefit, but only his proportion of the general benefits shared by all the agricultural community, it would be manifest that his subscription for life, would be of very inconsiderable amount, compared to his share of the general benefit to be thus derived.

QUERIES.

Queries on the following subjects have been addressed to us. We owe an apology for the long delay of the first, which was caused by unintentional oversight.

1st. What is the proper mode of thatching houses with straw? And would the practice be economical in Lower Virginia?

2nd. What is the best size, form, and model of fixing a roller, to be used on level and light land, for the purpose of giving the soil greater firmness by pressure?

THE FARMERS' REGISTER.

VOL. III. SEPTEMBER, 1835. No. 5.

EDMUND RUFFIN, EDITOR AND PROPRIETOR.

For the Farmers' Register.

OBSERVATIONS ON THE LOW WAGES OF FEMALE LABORERS.—No. 1.

The general depression of the wages of laboring females in this country, and the peculiar circumstances which condemn to unceasing toil, and severe privation, so large and meritorious a portion of the whole community, are subjects which well deserve the consideration of every one who has a share in the general interest. It is not only a matter calling for the action of the philanthropist—but it also has an important bearing on the public economy and national wealth; and *may affect*, if it does not already threaten, the private interest and family affections of every individual. This is as yet a country of plenty—one in which the industrious laboring man cannot fail to earn the necessaries of life, and in which the labor of a day will generally suffice to provide the bare necessaries of life for a week. Yet not content with the wages which demand and fair competition will always properly adjust, nothing is now heard of in the northern cities but the combinations, and "*strikes*," of bodies of laborers, and the resort to every means of intimidation, to enforce their unjust and lawless claims for higher wages, or for reduced hours of labor. It is not designed here to consider the operation of these combinations, or to show that, even when successful, the consequences would be injurious to those who seek benefit from them, as well as to their employers and to the community at large. The conduct of these full-fed, yet discontented and riotous laborers, is merely here named to be contrasted with the condition of the thousands of females, who, in silence and in hunger, and under fears of still greater miseries in future, labor incessantly to prolong a wretched existence. Why should such a difference in the rewards for labor exist, and be increasing in degree, between the two sexes? And are there no proper means of removing, or at least of alleviating the evil as it regards women?

Benevolent and public spirited men have recently taken this subject into consideration, and have commenced acting, with more zeal perhaps than discretion. It is feared that their efforts are not properly directed, and will therefore produce no permanent or beneficial result. Public meetings have been called, in Philadelphia, of the laboring females, and reports of the existing grievances have been ordered—resolutions entered into of the propriety and necessity of increasing wages, and a plan devised (as is inferred from the imperfect and concise statements in the newspapers,) for forming associations of females, like the "trade's unions" of men, to combine their wishes, and to *enforce* their demands. All this will be ineffectual—and much worse than merely ineffectual. The assembling of females in public meetings, is a violent departure from the retiring modesty which has heretofore distinguished our country women, the poor no less than the rich. By previous habits they are unfitted (and long may they remain so,) to take part in public deliberation and action. Even were it otherwise, combinations of females cannot possibly *compel* an advance of wages, as is often attempted and effected by associations of men—and if they could, the results would be liable to the same general objections. Without drawing together, for public gaze, thousands of the sufferers, it would be as easy to ascertain and make public their cruel oppressions. As to any number of individuals, resolving that they will pay higher wages, and adhereing to that course, it would merely operate as charitable gifts to particular persons, and could have no effect in curing the general evil. To do this, the causes must be removed: the evil must be attacked, not at the latest shoots of its branches, but at its root—which will be found in the habits and institutions of society in this country.

Why is it that, while mechanics generally in our towns can earn at least $1 for 10 hours labor, very many of the most industrious and competent female laborers, or mechanics, for 15 hours work, seldom earn one-fourth, if indeed one-eighth as much? The answer would be ready, if the occupations were such as to require the whole strength of a healthy man. But this is very rarely the case. In most kinds of mechanical labor, skill, dexterity, and patience, are more required than mere physical force—and women, if employed, would as well or even better than men, execute the same labors, and deserve at least as high rewards. But the misfortune is, that while every mechanical employment, save two or three, (those of milliners and mantua makers are perhaps the only exceptions,) are open to men, women in Virginia, and wherever manufactures are not in extensive operation, are confined almost entirely to sewing. There are at least as many poor women as of poor men—and the labor of half of all the portion of the community dependent on labor for bread, is *not only forced into one single employment, but is driven from the most profitable part of that employment, to make way for the other sex.* Men's clothes, by usage and fashion, have been almost entirely given up to be made by males—and in many cases, the male merely receives the price, while females, for a small proportion of it, actually perform the whole labor.

Now suppose that the tyranny of law, or of custom or fashion, of religious prejudice, or any thing whatever, compelled a very large proportion of the laboring men to confine their efforts to a business which one-third of their number could as well execute: would it not be a certain consequence that their competition and urgent necessities would depress their wages to the lowest possible state? If 20,000 shoemakers were enough to supply the wants of our country, and 40,000 other persons were compelled to make shoes, or to be deprived of all other employment, it is evident that the wages for this kind of labor, would be reduced as low as are now those of poor female seamstresses; shoemakers, almost without exception, would be reduced to the greatest necessity and state of suffering. If the proper and necessary number of the trade (which was supposed to be 20,000,) could have effectually combined, or any portions of them, to raise wages, it is as obvious as it is certain, that it could not be done when thrice that number had to share the employment and the wages, and were almost starving on the insufficient dividend. Therefore, combinations of women to compel the raising of the wages will be altogether ineffectual. as all such combinations are altogether wrong, and injurious in their tendency.

But the main reliance seems to be, that the persons who pay these stinted wages of labor, may be impressed with the enormity of the grievance, and voluntarily consent to increase them to a fair and reasonable demand. Doubtless many individuals are ready to yield to such promptings of benevolent feeling: but however numerous the cases may be, and however liberal may be the advance made on previous prices, the remedy for suffering will be but slight, and no remedy whatever will thereby be offered for the real evil—that is, the general and fixed depressed prices for female labor. By possibility, thousands of individuals may be induced to pay double prices. (and double prices would be required at least,) as wages for the employment which their private and personal demands would create—and thousands of deserving workwomen might thereby obtain a fair recompense for their toil, and an exemption from their previous sufferings. But even the occurrence of this rare (not to say impossible) exercise of charity, would not benefit the still greater number, who were not so favored by other employers—and indeed, would rather cause them increased injury. And no confidence could be placed in the permanency of even the very partial relief that would be afforded. It is an established truth, that prices for labor, as for commodities, will always be regulated by the proportion of supply and demand—and that they never can be materially affected, nor for any length of time, by any other considerations than the *interest* of the contracting parties. Laborers, as a body, will always take as high wages as they can obtain—and their employers will give no higher than the lowest which will suffice to command the services required. This general operation of such causes, if properly considered, will show that no relief can be hoped from any voluntary offers of increased wages.

The remarks which have been submitted, apply more particularly to the state of society in Virginia, and other parts of the United States where there are few or no factories which call for female laborers. When such factories are introduced extensively, they extend the field of woman's labor, and serve to increase their wages—at least in the beginning. But it is found, ultimately, that one evil has only been exchanged for others of not less weight. However, it is not intended here to enter upon the consideration of such changes in habits and industry—but only of society and habits as existing in a community not much advanced in manufactures.

Except in towns, it is literally the case in Virginia, that poor females have no employment whatever, by which they can gain wages, but in sewing. Weaving and knitting formerly furnished more employment, but now scarcely any worth naming, on account of the improvements in weaving on a large scale, and the consequent reduction of price. As the small proportion of sewing which is shared among the many who would gladly be employed, would not suffice for one-fourth of the hands, it follows that three-fourths of their time, on the general average, these laborers are without employment, and cannot obtain it even at the lowest pittance which is even paid for it. These females are often as respectable and as deserving as any of the more wealthy—and who are indebted to the kindness of some relative or friend for a home. where if they eat the bread of dependence, it is at least received from kind hands. Without such aid, and with nothing but their wages of labor to sustain them, thousands of such females would starve, or be driven to live on public charity. Many among these are the widows or orphan daughters of highly respectable men—many even of men who had enjoyed wealth. And there is not a farmer in Virginia, whether rich or poor, who can feel sure that in two generations, if not in one, that some of his female descendents will not be in the same deplorable situation: a situation to a sensitive mind, which cannot be otherwise than most galling and distressing, however tempered and alleviated by kindness and affection. A state of dependence, when not so alleviated, condemns the poor woman to the unremitting toil of the day laborer, without his wages—to the subjection of the slave, without his freedom from care and mental suffering. This is the situation, in its various grades, in which thousands of the most industrious, virtuous, and deserving part of our population are placed—and the danger of which is pending over as many others, who are now growing up in hope and joy, cherished by affection, and supplied with every present comfort. And the beings who are condemned to this state, and who succeed each other in endless succession, and increasing in numbers and in wretchedness, form a portion, (and an equally deserving portion) of the "better half of the human race"—who as a class, are flattered, almost adored by men, and yet denied by their usages and institutions, the means of earning honest bread, and in numerous cases, are deprived of all the means of subsisting, except in a worse than slavish state of dependence—or in a life of infamy.

If we were neither husbands nor fathers—if we cared nothing for the situation of unfortunate females who are not connected with us by ties of relationship—still as members of the community, all men have a deep interest that so much of the country's capital of labor and talent, should not be kept idle and useless, and a source of expense, instead of profit and wealth to the nation.

POLECON.

July 3*rd*, 1835.

[Deeming that (for the present time) enough of argumentative writing against the policy of the existing law of enclosures, has been given to our readers, we have withheld from publication more than one such communication recently received. A similar course would have been pursued with regard to the following, but for the matters of practice contained, which present a different kind of claim to notice. The experiments would have been of more value as examples, however, if authenticated by the author's name, and would have served his purpose better as proofs of the positions maintained.]

For the Farmers' Register.

A WORD TO "FENCEMORE,"

Who in the May No. of the Register, Vol. III. page 47, "insists that agricultural reform calls for no legislative enactment—that the existing legal policy" (as regards fences) "throws no obstruction whatever in the way of the individual who sincerely wishes to place his stock management upon a profitable footing, and that he feels constrained to condemn all such attempts on the part of the legislature as gratuitous and uncalled for, and as oppressive in the extreme to the whole body of small farmers, who constitute so large a portion of the agricultural community."

"Agricultural reform calls for no legislative enactment"—and Fencemore seems to think that he has satisfactorily established this proposition, because he has adjudged that he would do better with just *double* the quantity of fencing now used —and as we are now *compelled by law* to have a certain extent of fencing, he would by no means remove this *compulsory enactment*, least, as it would seem, we should attempt to do with *less*, when it is his opinion we ought to have *more*. It matters not what other honest farmers may think, or to what conclusions their arithmetic may lead them. The *true interest* of the farmer, and his *sagacity* in pursuing it, is not enough to direct him in the management of his own private affairs—he must be made to keep up his fencing about his arable lands at all events, by "*legislative enactment*." Fencemore has demonstrated arithmetically (if indeed he has demonstrated any thing) that it will take as great an extent of fencing to enclose a proper number of lots for standing pasture and other purposes, upon an improving system, as is now used for the outside enclosure of our arable lands—and thus as nothing could be gained in the actual amount of fencing, supposing the present law of enclosures modified, (which by the by we do not believe) he concludes that nothing can be gained in any way—or because we should have to make fences around a few lots for pasture and improvement, we had as well make them around our whole plantations! Thus doubling our amount of fencing, and for what? Why, according to Fencemore, to keep "the country from being thrown into consternation and dismay by a drove of hogs or bullocks!!" Or at another place, because "it would be oppressive in the extreme to the whole body of small farmers," for the legislature to take away from them the power to turn their hogs and cows on their neighbors' fenceless crops. Or again, because "the annual *clearings* of the tobacco planter are utterly inadequate to his immediate demands," this tobacco planter must therefore be permitted to use the woods as a range for his stock, having no open land; thus entailing upon his neighbor, perhaps a cotton planter, with an abundance of pasture of his own, the enormous expense of keeping up double as much fencing as he ought to have. solely for the benefit of the tobacco planter's half-starved hogs and cows. This argument of Fencemore seems to us to afford but a poor "defence of the law of enclosures" —and we think it will be found to weigh still lighter against a few *stubborn facts* which we are now going to state, and which we think ought to go farther than arithmetic with the "whole body of small farmers," and that of the big ones too, to prove that it would be best for every man to live upon his own land, and within his own fences.

First. A few years past an ox was put into an old barn about the first of December—kept well littered and fed till the first of March following. Upon hauling out the manure, it was found that that taken from the barn was equal to that made by six of the *out cattle* at the pens; and it is believed to have possessed twice the strength that the pen manure did.

Second. Several winters past, six cows were milked—fed in the usual way with dry shucks scattered over the pen. The next winter two only were milked—fed throughout the winter upon one quart of meal each, morning and night, mixed with cut shucks, and wet with salt water. These last two gave *more* milk, and that richer, than the six gave the winter before. The next winter, but one cow was kept to milk, which was well fed with meal, cut shucks, and a few cotton seed. Her calf was killed, and she was milked three times each day. She gave nearly or quite as much milk as the two, or the six before kept gave, and was turned out in the spring quite fat.

Third. In the spring of 1834, ten shoats were put into a small pen, and fed through the summer upon clover cut from half an acre of land, together with one ear of corn each every day. They kept in good order, and at fattening time in the fall, were found in better order, and fattened upon less corn, than those that ran at large; although these had the same quantity of corn each day whilst out—one-eighth of these last having died from the time the ten shoats were put up. When killed and weighed, the ten hogs which had been put up in the spring as shoats, of the same size and age as these which were running at large, weighed from 27 to 35 pounds, each, more than the hogs which these last made, although fattened in the same manner. It was moreover observed, that at least *six times* as much time was required to look after the *out* hogs, as was required to feed and water those in the *pen*.

By these experiments then it would seem that we in fact gain nothing by permitting our stock to run at large, even as regards *their benefit*, to say nothing of the enormous expense which the present *ad libitum* system, as regards stock, entails upon the whole agricultural community. We have just seen that one cow tolerably well kept upon a man's own land, and within his own fences, is worth six running at large—that it will make him *more manure* than six—will be a finer animal than any of the others, and will bring him better calves. That his hogs may be kept up upon the same amount of corn; and with the addition of a little clover, will keep fatter, grow larger, be less apt to die; to be killed or stolen, and will give him more meat, and be fattened upon less corn than the same number running at large. And above all that time which, with industry, is a poor man's capital, is saved to him in the ratio of six to one, when he keeps up his hogs.

FENCE LESS.

June 30th, 1835.

GYPSUM NOT INJURED AS MANURE BY BEING HEATED.

To the Editor of the Farmers' Register.

Fairfield District, S. C., July 11th, 1835.

Impressed with the justness of a remark of yours, that "information obtained from statements in detail of agricultural experiments, is far more satisfactory to the attentive and laborious inquirer, than a mere report of the general opinions of the experimenter," and in accordance with that spirit, I now offer you a brief account of an experiment, which perhaps may not be uninteresting.

In the spring of 1834, intending to plaster a lot of orchard grass, I ordered a few barrels of gypsum from Charleston. As I had before found the process of pulverizing the stone rather troublesome, I requested my factor to purchase the gypsum already ground into powder. When the gypsum arrived, I was astonished at the high price it had cost me, to wit, six dollars per barrel; but not suspecting the judgement of my factor as to the quality of the article, I made no examination of it myself, but placed it entirely to the account of imposition. In June I had it spread over the grass at the rate of one bushel per acre. The very next day after having spread it, a plasterer who it seems had previously examined the plaster, called on me to ask the favor, as the article was not to be had in the Columbia market, of a barrel of it, to finish a job of stucco-work in which he was then engaged. I told him there was still a barrel on hand which he might have, but that it was raw gypsum, and that he would have to put it through the process called "boiling," before he could use it. He replied that it had already gone through that process, and was excellent plaster for his work. I denied the fact, as I had bought it for simply ground gypsum. He, however, instantly undeceived me; and convinced me, by working a little of it into plaster, that he was right; upon which he took the barrel, with which he finished his job of stucco-work.

As I had never seen any account of the application of gypsum in aid of vegetation that had undergone the process of heating, it at once occurred to me that I had probably destroyed my lot of grass. Reflecting a moment, however, upon the effect of heat upon gypsum, it was obvious that it had undergone no essential change in its component principles, except the expulsion of the water of composition. It was still the sulphate of lime in a more concentrated and condensed state; and as in this state its avidity for water is so prodigiously great, I concluded the first rain, or perhaps the dews, would soon saturate it, and re-convert it into its natural state of gypsum; and, therefore, I could not conceive how it could injure the grass, unless from an over-dose of gypsum in consequence of its greater strength to the bushel, of which I felt but little apprehension. In a few days afterwards, upon receiving one of the numbers of your Register, I was gratified to find you had opened a discussion upon the same subject, the first which I had ever seen; and so far, in the absence of any experiment, the same conclusion had been arrived at by yourself.

My accidental experiment, however, I think goes far towards settling the question. The grass never showed any signs of unhealthiness, or suffered in any way for a moment; but on the contrary, from the manner it sustained one of the severest droughts ever witnessed in August, and again the unparalleled cold of the last winter, and the manner in which it has subsequently flourished, and retained its verdure, I am satisfied the mistake was all in favor of the grass. I had applied gypsum to a part of the same lot in June of the year preceding. The benefits were very manifest, but not equal to those from the last plastering. In 1832, I applied it at the rate of about one bushel per acre of unheated gypsum, and it was my intention to apply only one bushel per acre in 1834; but by the mistake, as gypsum contains 22 per cent. of water, which had been driven off, I of course applied what was equal to one bushel and nearly a quarter of the unheated article; which the result has shown was not too much.

The great objection then to the application of gypsum that has undergone the process of heating, as a fertilizing substance, consists in the expense, and not in any deleterious or impaired qualities of it—which expense at the rate I paid, was far too great. The heated plaster cost me about two dollars per bushel, whilst I never paid higher than ten dollars per ton in Charleston for the gypsum in stone, and have bought it as low as seven dollars.

J. D.

P. S. As it is satisfactory, and generally useful to know all the circumstances attending an experiment, I will mention that the lot on which my grass grows is new land, on a ridge of pretty good soil, with a growth of oak and hickory, in Fairfield District. It is what we call clay soil mixed with a good deal of feldspar stones; but sufficiently silicious to be easy of cultivation. It is shaded by the natural growth of lofty oaks, &c., left standing about 50 and 60 feet apart. It has had no manure except two annual supplies of cotton seed, spread at the rate of two wagon loads (45 bushels each) to the acre. The grass is flourishing and profitable.

From the Claremont National Eagle.

CANADA PLUMS.

The plum trees all over this section of the state and in the adjoining parts of Vermont present a most singular appearance. The fruit at this point of the season, unless injured in some way, should be about the size of a pea—perhaps not so large. But the fruit every where presents a most unnatural size, presenting rather the appearance of green lemons than anything else we can remember, swollen, wrinkled, and puffed up, some long, others round, an inch long and nearly as thick. They are of a bright green or yellow color, tinged with a beautiful scarlet on the outside, while they are completely empty within. This fruit—the large red plum—in the natural course of vegetation is at this time, as we remarked, about the size of a pea; and those who have plum trees, as there are many on the Connecticut, are exceedingly puzzled to account for this state of things. We had a branch brought to this office from Cornish which really has a very curious and singular appearance. We are informed the trees have some ten years back suffered in the same way, but the cause is a mystery. Nothing like a worm is to be found in the swollen fruit.

From the United States Philadelphia Gazette.

YOUNG'S PATENT SPARK CATCHER FOR LOCOMOTIVE ENGINES.

Mr. Editor—At a time like the present, when the extension of rail roads throughout our country is becoming so general, and the employment of locomotive engines has become a matter of course, I deem it important that all persons connected with the management of rail roads should be made acquainted with the fact, that a complete remedy exists for the greatest nuisance to which this mode of travelling is liable, viz: the emission of sparks from the engine. That remedy is to be found in the contrivance with the name of which this article is headed, and the patentee is prepared to dispose of the right of using it, either at a reasonable rate for each engine, or at a gross sum, to be paid for the privilege by each company that may be desirous of availing itself of his invention.

It is now upwards of two years since the spark catcher of Mr. Young* has been in use on the New-Castle and Frenchtown rail road, since which period no instance has occurred on that road of a single garment having had a hole burnt in it by a spark from a locomotive engine. Of the tens of thousands of persons who have travelled the New-Castle road during the period named, not one can be found to gainsay the above statement.

Is there a single person, who has travelled on any other road in the United States, on which locomotives are used, with wood for fuel, that has not been annoyed, and either had his flesh or clothing burnt during his journey, by the means I have mentioned? I do not believe there is one to be found.

Is the Camden and Amboy road free from the intolerable and dangerous annoyance? No!—Baggage cars have been burnt, passenger cars have been on fire, and ladies almost denuded.

Is the great thorough fare of Pennsylvania, the Columbia rail road, free from it? No! Barns, wood, crops of grain, and fences, have fallen beneath the flames in turn.

Are the Philadelphia and Trenton, the Philadelphia and Germantown—in a word, are any of our rail roads in the whole country, from Maine to Louisiana, provided against the inconvenience and danger of which I am speaking? No! not one.

We have arrived then at this point; the greatest drawback to the pleasure and safety of travelling on rail roads with locomotive engines, is fire emitted from the chimnies of the engines, and against this a perfect preventive exists, the right to use which may be obtained by any company that see proper to purchase it, at a reasonable price. One company only in the United States has availed itself of it. The question for the public to decide is, whether they will suffer this sort of carelessness or false economy to prevail in rail road boards any longer, and allow their own property and lives, and those of their wives and children, to be jeoparded, or whether they will resolve with one accord to prosecute in all cases of damage the company that undertakes to convey them safely without taking the proper precautions to do so.

The writer of this article is as ardently attached to the rail road system as any man in the country. He has long looked on the monstrous abuse, he is now noticing, in silence, but a solemn sense of duty, quickened by a recent signal illustration of the danger to which life is subjected by neglect in guarding against the particular evil of fire, has at length urged him to break his silence.

And I hope that this brief notice may induce a general attention to the subject, which is one, in my humble judgement, of paramount importance both to the corporations alluded to, and the public.

One word more. The assertion is distinctly made, and all contradiction of it defied, that Young's Spark Catchers are a perfect preventive to the emission of sparks from the chimnies of locomotive engines when in use. I believe it might be asserted with equal safety, that no other contrivance has been found to answer at all.

L.

June 16th.

* Mr. Young is the engineer of locomotive power on the New-Castle and Frenchtown road, and resides at New-Castle.

TO DESTROY LICE ON CATTLE.

To the Editor of the Farmers' Register.

In the June number of the Register, I perceive several modes recommended for destroying lice on cattle, each perhaps, efficacious, but with some objections: and as we cannot have too many remedies for the destruction of that pestiferous insect, allow me to recommend the use of a little flour of sulphur, given internally, once or twice a week, with salt, which is eaten kindly. This I have practised with great success.

In addition to the beneficial result in destroying the lice, it has the happiest effect on the general health of the cattle.

H. H. C.

For the Farmers' Register.

SUPPOSED MISTAKE AS TO HESSIAN FLY.

Essex, July 22, 1835.

From the severity of the winter and the destruction by what we term the fly, our crops of wheat are reduced to about one-third of a crop. I have, on examining the stalks of wheat during the spring, seen a great number of deposites near the root; and at the approach of summer I found they had all matured, and deserted their winter quarters. I have looked diligently for the Hessian fly, but can see nothing but an innumerable quantity of grasshoppers of the smallest size. Indeed from the slight observations which I have made on this subject, I am brought to the conclusion, that we may probably be condemning the one for the fault of the other. I would beg, therefore, should any of the writers for the Register make a farther experiment with this deposite, that they will keep the insect till they are thoroughly convinced whether in fact it be the Hessian fly or not, for between the grasshopper in its youngest state, and the Hessian fly, there is a striking resemblance.

H. H. R.

EXPERIMENTS WITH LIME AS MANURE.

To the Editor of the Farmers' Register.

Norfolk Co., July 6th, 1835.

In my first acquaintance with the use of lime, I was almost driven from a further trial of it, by its contrary effects; but I candidly admit that my expectations were founded upon gross ignorance of the proper manner of using it, for I ought not, upon neither rational nor scientific principles, to have expected a different effect after the manner of use.

I will give you a history of my mode of application and its effects, if you can have patience enough to follow me, for I really expect you to be, tired reading such crude unpolished stuff as I am truly ashamed of myself: but the experiment is correct. If my pen has a poor faculty of relating it, your repeated assurances that doctrines when founded upon correct observation, was the greater object of your solicitude even if clad in homespun language, have spurred me onward to give you this desultory statement. In the spring of 1834, a very poor lot of land containing 15 acres, rather on the sandy order, what is termed by your Essay a sandy loam, was divided in two equal lots of 7½ acres each, both to be seeded in red clover to experiment from, with lime and plaster separately. As my knowledge of the effect of either, was rather vague and visionary, I determined to improve it if I had to pay rather dear for my whistle. Consequently 500 bushels of well burned shells was set apart for the lot for liming, and from 20 to 25 bushels of ground plaster was set aside for the lot for plastering. After the lot for lime received its first fallowing, it was checked off carefully at different distances so as to vary the quantity when spread from 40 to 120 bushels per acre, a bushel of the shells was put down in each check, and carefully covered over with earth until they had perfectly slaked, and then spread as regularly over the surface as possible. The other lot received a light broad cast of rich dunghill earth, and seeded both lots about the middle of February in red clover, prepared as neatly as a harrow and roller could do it. In March following, the lot destined for plaster, received its first due 1½ bushels to the acre sowed on a damp day, and the next plastering after the first cutting of clover was taken from it: the two lots were left to time and seasons to unfold their wonders. The limed lot with a good grass season did manage to admonish the passer-by that red clover seed had been sown there. The other yielded in the month of July, a very fine cutting of hay. So much for my first attempt. The difference was so very striking that it awakened in me an anxious inquiry. I commenced to read—for until then I looked upon a book on agriculture, like the laymen did the Bible in the darkest days of popery, to be touched at the risk of ruin. I had embraced the ruinous idea so common, and yet so fatal to my countrymen, that book knowledge was prejudicial to profitable husbandry: but I soon detected my error, and determined to carry my experiment with lime still farther. So, last October I carted on the lot 500 loads of good farm pen litter, and spread it broad cast, then seeded it again with wheat and red clover at the rate of 1½ bushels of wheat and 5 quarts of red clover seed to the acre. Now comes the bright side of the picture. The wheat (on land before almost too poor to produce any thing) stood on an average, from 5 to 6 feet high (though a very bad season for wheat;) and I verily believe, could it have been prevented from falling down, the yield would have been from 175 to 200 bushels. I know not the exact quantity I have saved, not having yet thrashed it all out, but it will not fall much short of 175 bushels, and the waste was considerable. The clover bids fair to excel the other lot, though the yield from the plastered lot was not inconsiderable, as the first cutting this season averaged from three to four feet in height, and is now fit for the scythe again. So much for lime and plaster. Many of my neighbors when passing these lots look puzzled. The cloud of ignorance which has so long obscured Eastern Virginia is gradually disappearing before the effulgent rays of your agricultural pioneer the Farmers' Register, for such I hail it in this section of the country.

Whilst my hand is in I will give you some account of a small crop of corn which I have growing, and for a more appropriate name will call it the experiment crop. I do not expect this to excel or even to compete with overgrown crops that have been made at the north; because the number of stalks to the acre is not great enough to afford the requisite number of ears: but I am not so certain but what corn might be planted thick enough to afford to the acre as great a product as has been raised at any other place. The land the crop is now growing on, was originally very poor, but was made rich for a crop of the skinless oat: being disappointed in obtaining them, I determined to plant it in the extra prolific or twin corn, which is said to produce from five to eight ears to the stalk. The corn was planted on a deep trench filled with rich dunghill earth three feet by eighteen inches, and the corn covered with an equal combination of leeched and unleeched ashes: it was with great difficulty that the corn was made to stand from the caustic effects of the ashes, but the whole is growing finely and bids fair to produce well. If it does not suffer from being too thick, the yield must be considerable: the result, if deserving of public notice, you shall hear as soon as ascertained.

A. S. F.

From communications to the Board of Agriculture.

OBSERVATIONS ON THE UNITED STATES OF AMERICA.

By William Strickland, Esq. of Yorkshire. Received 8th March, 1796.

[Concluded from p. 211 Vol. 3.]

VIRGINIA

Is the southern limits of my information in America; beyond it inquiries were unnecessary, because it appears as if agriculture had there already arrived at its lowest state of degradation.

The usual crops, in this state, are maize and wheat alternately, as long as the land will produce them tolerably well; then in future after the two crops, three or four years rubbish pasture; and in parts where tobacco is cultivated, several crops of it are taken on first clearing the ground, before any grain is sown upon it; now and then a crop of oats intervenes, perhaps instead of wheat, perhaps following it; clover and lucern are yet little known, though there is reason for supposing that they would be as beneficial here, as the first is, in the other states, or perhaps more so; since, on account of the increasing heat of the climate, pastures and meadows are more precarious, and less frequent. Where crops of wheat, of not more than five or six bushels per acre, are expected, it is not usual to sow more than half a bushel of seed, and no where in this state more than one bushel. The average of all that part of Virginia lying east of the Blue Ridge, I am satisfied I state at the utmost, at seven bushels per acre; no one states the average of that extensive flat country in Virginia, lying below the head of the tide, at more than five or six bushels; it therefore requires much better crops in that naturally fertile, but worn out, and not extensive tract of red land, at the foot of the mountains, to raise the average to seven bushels. In those fertile and beautiful vallies that lie among the mountains, in which ignorant cultivators have not yet resided sufficiently long to have entirely exhausted the soil, favored with a temperate and delightful climate, it yet produces crops equal to any in America; I have reason to believe not less than twelve bushels per acre; but the surface, capable of cultivation, when compared with the rest of Virginia, is very small indeed: with the country beyond them I am unacquainted. The average of maize, in the eastern part of Virginia, is not to be reckoned at more than fifteen bushels; of the vallies, at twenty bushels; of oats, from one and a half to two bushels of seed to the acre, will be a return of from twenty to thirty.

All the back country of America is very favorable to the growth of rye; crops, producing from twenty to thirty bushels, are commonly met with; this grain is entirely consumed in the distillation of whisky, chiefly for the consumption of the Irish frontier-men, except among the Germans in Pennsylvania, who use it for bread.

Much of the wheat of this state is of a very inferior quality, some so bad as scarcely to be of any use, though that which is good, naturally much resembles the wheat of Maryland; but the slovenly management of the farmers considerably lessens the value of it.

The use of the flail is scarce known here; almost all the wheat is trodden out in the field by horses upon the bare sandy soil, with which much of it gets incorporated, and afterwards is separated from it by sieves, or some other means that answer the purpose; the consequence of this is, that a considerable quantity of dust adheres to the surface of the grain, and insinuates itself into the groove on one side of it, so that no art can entirely clear it away; and thence I am told millers are unable to make superfine flour from Virginian wheat; and on that account, that it bears a price, inferior to what the quality would otherwise demand. A weevil, or some other insect, greatly infests the wheat of this state when in the straw, which makes it necessary to tread it out as soon as possible after harvest; and this is frequently attended with inconvenience and loss. In unloading the wheat of this state from shipboard, or otherwise working among it in the granaries, the people employed are frequently so affected with a *prickling* or *nettling* on the skin, as to be unable to go on with their work, but without being able to account for the cause of it. I recollect a similar circumstance happening, in unloading a vessel laden with Virginian wheat, some years since at Liverpool, when it was said to be caused by a minute insect. Oats are not extensively cultivated in any part of America, and are every where bad, but those of this state, of the worst possible quality: they have certainly kernel sufficient to enable them to vegetate, but are, notwithstanding, light as chaff. The cultivated oat appears again returning to the original grass. I never saw any oats that would be marketable in England, except some in the German tract in Pennsylvania, and they would admit of comparison with such only as we should esteem very moderate.

I am unable to discover how profit is to be derived from such crops, unless, that people being actually possessed of the soil, and of the slaves to cultivate it, abandoning all expectation of profit for their capital, look upon all as nett profit that is received from the land. The land owners in this state are, with few exceptions, in low circumstances; the inferior rank of them wretched in the extreme. The evils of slavery are now rapidly and forcibly recoiling from the slave upon his owner. Tobacco and maize, which heretofore have been the curse of the slaves, are now, with the slaves, allowed by all men in Virginia, to have been the ruin of themselves and their country: the almost total want of capital, among this description of people, forbids all improvement on a great scale, and want of the knowledge of agriculture, prevents its slow but certain progress. To show what some of this land would submit to before it became exhausted, and the mode pursued to accomplish it, I will take the cultivation of a gentleman, possessing a considerable tract of land, originally as fertile as any in nature, on the foot of the Blue Ridge, who complained that much of his estate was worn out. After clearing and burning the woods, seven crops of tobacco were taken, in as many years; in some instances, ten crops; four crops of wheat; and ten crops of maize and wheat alternately, in ten years. After twenty-one years, the land refused to yield any more grain; but in a twelvemonth, too benignant nature clothed his property with a matchless sheet of white clover.

To such modes of cropping, the poverty of the people, and sterility of the soil must be attributed: crops may be seen where each ear, frightened at its neighbor, keeps that awful distance, which would admit of a person's walking through the field without breaking down a stalk, in a climate and soil well calculated for the produce of wheat. In many of the states, the Hessian fly bears the blame, which, if properly placed, ought to stand to the account of the ignorant and greedy land owner; but no one pretends to say, that this insect has committed any material (if any) depredations on this state.

RECAPITULATION.

	Average produce of wheat.	Maize.	Buckwheat.
	Bushels.		
In the state of New York,	12 per acre	25	15
Jersey, Pennsylvania, Delaware, Maryland,	8 ditto		15
Virginia (east of the Blue Ridge,)	7	15	25 oats
Ditto (west of ditto,)	12	20	25

The average of the above, according to the number of districts, is nine bushels and three-quarters of wheat per acre; but as the first and last district, which are the most productive, are considerably less in extent than the two which are the least productive, the average of the whole, in proportion to the extent of surface, cannot be estimated at more than nine bushels per acre; to the other crops it is not necessary to pay attention. Now, that a country situated in the finest latitudes of the globe, with a soil certainly, by nature, as capable of producing, as the climate is of bringing to maturity, far greater crops, and certainly, in both respects, better calculated for grain than many parts of Europe, which produce from double to treble the quantity on an average, should yield crops which there, would be looked upon as scarce worth the collection, renders the cause of it deserving of our notice.

When inquiring into the subject, among the most intelligent people of the different states, I found this inferiority pretty generally attributed to a deficiency in the vegetative powers of the soil: it was said that a country, fresh out of the hands of nature, was not fertile; that it would bear a few tolerable crops when first cleared, but soon ceased to do it; and that it required the cultivation of ages, to render it as fruitful as old countries; so little were the best informed aware of their own defects, or the merits of the soil, or willing to acknowledge either of them. Some of the northern states, who remembered the days of greater fertility, attributed the visible decline to the depredations of the Hessian fly; but in Virginia, they scarcely know this insignificant animal, and therefore on it cannot cast the blame; and Virginia has probably experienced a greater failure of crops than any other state. In Virginia, this gradual decline has not injudiciously been ascribed to the culture of tobacco and maize; the first it has been observed, enriched the planter, but ruined the soil; the last ruined both; but the culture of tobacco and maize, as the staple articles of the country, has only been partial, being confined to some of the southern states, while the decline has pervaded the whole of them; therefore, however injurious these may have been, we must look deeper for the root of the mischief: that I venture to state, as likely to be found in *the present constitutions of the states, and the manners of the people.*

Before the revolution, I have reason to believe that the average produce of the soil would have stood considerably higher than at present, and there is no doubt that the owners of it were more opulent: at that time, the capital of the country was vested in the lands; and the landed proprietors held the first rank in the country for opulence and for information, and in general received, the best education which America, and not unfrequently Europe, could afford them; their estates were sufficiently extensive to make it worth their while to bestow their time and their money upon them; and the estates in return repaid with interest the attention and expense. The law of England* generally prevailed with respect to the descent of property; an aristocracy was formed of capitalists, well calculated for improving, cultivating, ornamenting, and enriching the country; great exertions and great improvements cannot be made in any country but by persons of this description; and no country requires such exertions and such improvements, as a *new one.* Since the revolution, a new order of things has taken place; new people, and people of very different occupations and pursuits, have taken the lead in the government, both of the confederation and respective states. The capital, as well as the government of the country, has slipped out of the hands of land owners; and these new people are now employed in very different, and, in the present state of things, more productive speculations than the cultivation of lands; in speculations frequently at variance with the best interests of the country. In some of the states, the gentlemen of landed property have passed into perfect oblivion; in none of the states do they bear the sway, or even possess their due share of influence, except perhaps in those of New England; and there, they only take it incidentally, as the lands are divided with much equality among every description of people, and are rather a secondary object, even with the principal people of the country, who generally, with a small occupancy of land, are obliged to follow other more lucrative pursuits, on which they place their chief dependence.

Before the revolution, real estates descended to the eldest son; the law, since that period, has ordained an equal division of them among *males and females* in equal degree, except in one or two states, where the eldest son takes two shares. This law has already had a very extensive, but a very mischievous influence; it has had the effect which the authors of it intended, in introducing a greater *equality among the people*; but it has had another also, which they might not have foreseen, and could not have intended; that of reducing them to *an equality of poverty, and their soil almost to a Caput mortuum.* Fewer people of landed property of any considerable opulence, are to be met with, than heretofore, and their numbers must be continually diminishing, from the influence of this law of descent; for though some people will not from custom acquiesce in it, and the wisest, from

* In the state of Connecticut real estates were always divided, as at present, among the children, male and female, the eldest son taking two shares; the evils, however, of minute division of real property, are there fully perceived and felt at this time.

a sense of the evils arising from it, which they already feel and lament; yet the law will occasionally have its course; and the estate once divided, can never again be united. The consequence of this is, that landed property is no longer an object of profit or pleasure; few choose to possess more than is necessary for their own convenience; fewer live in the country than heretofore; no houses, in many parts of the country, of any consideration, are building; and no improvements of any kind taking place. With the decline of this class of people, and their property, is also that of the produce of the soil; for the poor and the ignorant must unavoidably wear it out; the opulent and the intelligent alone can improve and ornament their country, and increase the produce of it. Such is the operation of the new constitutions on the higher orders; and it will be found, that manners too, have their full influence on the inferior orders; the mass of those we should call planters or farmers, are ignorant, uneducated, poor, and indolent: such an one who possesses an hundred acres of ground, will not in stock, furniture, or property, be worth £60; were he to possess such a capital, he would be esteemed a person of considerable substance; but he *boasts of his independence, and enjoys inaction.*

Of the people of this, and of inferior ranks, ease is the greatest bliss, and a frolic the greatest spur to activity; with such inclinations, labor will afford but a bare subsistence; and with this, such people will sit down contented rather than toil. From this picture, must be entirely excepted the people of the New England states; they, with a more rational love of independence, possess also an equal love of industry and order; consequently this exemplary and enterprising people, enjoy the natural attendants of such principles, knowledge, wealth, and power, in full proportion to their respective stations. The consequence of this state of things cannot be otherwise, than that the produce of the country must be stationary, if not on the decline; and that the supplies hereafter to be drawn from this, by other countries, cannot be greater, if so great, as they have been, unless some sudden and very material alteration of public principles and private practice should take place. It may account also, in part, for the excessive price which a demand not excessive, and no very great supply, has created in most articles of export from the United States, and especially within the last two or three years; and it may perhaps also appear, that this increased demand, and excessive price, have not materially added to the quantity exported* of articles

* The following is an account of the export of the staple articles of the United Sates, in the first and last years, in which it can at this time be obtained; in the first year, public disturbances in Europe had not had any material influence on commerce; in the last, a vigorous and general war had called for all the supplies that America could afford.

Year ending Sep. 30.	Maize. Bushels.	Tobacco. Hogsheads.	Cattle.	Horses.	Rice Tierces.	Flour. Barrels.	Wheat. Bushels.	Beef. Barrels.	Pork. Barrels.
1790	2,102,137	118,460	5,406	8,628	100,845	724,623	1,124,458	44,662	24,662
1794	1,472,700	72,958	3,495	1,828	*134,611	828,405	696,797	97,779	47,242
Loss,	629,437	32,402	1,911	6,800			427,661		
Gain,					33,766	93,782		53,117	12,780

* The return of this article being defective in 1794, that of 1793 is here taken.

The United States are therefore

Losers.

	Dollars.
By maize, at ½ dollar per bushel, -	314,718,5
By tobacco, at 40 dollars per hogshead,	1,416,080
By cattle, at 20 dollars each, -	38,220
By horses, at 40 dollars each, -	272,000
Buckwheat, at 1 dollar per bushel, -	427,661
	2,468,779,5
	1,657,982,25
	Dollars—810,697,25

Gainers.

By rice, at 18 dollars per tierce, -	607,788
By flour, at 6½ dollars per barrel, -	609,583
By beef, 6¼ dollars ditto, - -	331,981,25
By pork at 8½ dollars ditto, - -	108,630
	Dollars 1,657,982,25

The dollar 4s. 6d. sterling.

Therefore, though a bounty from 50 to 100 per cent, has been offered on the export of their chief articles of produce, in that great increase of price that was paid for them in 1794, yet in five years the United States have declined in the value of their export to the amount of upwards of eight hundred thousand dollars, according to the peace price. The price has augmented the export of articles of chief demand by the belligerent powers, but an immense loss in other articles, the produce of their soil, so as to leave the above great balance against the owners of it. If this be fairly stated, and the writer apprehends that the authorities from whence it is derived, cannot be disputed; surely it behoves the government of the United States to pay more attention to the landed and agricultural interests of their country; to remedy principles of law, so destructive to them, to occupy their minds on certain and immediate benefits, rather than attend to uncertain and distant speculations, before habits have become fixed in the mass of the people, which cannot afterwards, when wanted, be counteracted; before the principal people have abandoned a country life, as no longer affording them an occupation worthy of their attention; before their estates cease to be objects of rational pleasure, by being split into portions no longer worth possessing; and before they feel that their property and pursuits no longer afford them that influence, which their rank in society ought to give them.

of primary necessity to the countries demanding them, which they would have done, had the supply been naturally adequate, or capable of being forced.

"The husbandry of every country depending mostly on the market for cattle and sheep, and wool; how far is the bad culture of America owing to a want of them? Is there a demand for beef, mutton, and wool, in any quantities for exportation, or otherwise? And how far does the existence of these circumstances, in the vicinity of large towns, remedy such bad cultivation?

The answer to this has, in a great degree, been anticipated in the answer to the last question: what further is requisite, will be found in detailing the prices of articles in the different parts of the country when I was there.

1794, September. New York city. Beef, $3\frac{1}{2}$ $\frac{3}{16}$d. to $3\frac{3}{4}$ $\frac{1}{16}$d.; mutton, $3\frac{3}{4}$ $\frac{1}{16}$d.; veal, 5 $\frac{1}{16}$d. to $5\frac{1}{2}$ $\frac{3}{16}$d.; lamb, per quarter 2s.; pork, 5 $\frac{4}{16}$d.; pigs, live weight, $2\frac{1}{4}$d. per lb.; butter, 1s. $1\frac{1}{2}$d. new milk $3\frac{3}{4}$ $\frac{3}{16}$d. per quart; chickens, 10d. to 1s.; hay, £2 5s. to £2 16s. 3d. per ton; wheat. 5s. $7\frac{1}{2}$d.; barley, 3s. $11\frac{1}{4}$d.; maize, 2s. $9\frac{3}{4}$d.; rye, 3s. $1\frac{1}{2}$d.; oats, 1s. $8\frac{1}{4}$d.; per bushel.

New York State. Beef, 3 $\frac{6}{16}$d.; mutton, $2\frac{3}{4}$ $\frac{4}{16}$d.; butter, 9d.; wheat 5s. 4 $\frac{3}{16}$d.; pair of good oxen, five or six years old, from £13 10s. to £14 12s. 6d.; three years old, £6 15s. per pair. Fat sheep which may weigh 14lbs. per quarter, 6s. 9d. each; wool of good staple 4lbs. per fleece, 1s. $5\frac{1}{2}$d. per lb.

1794, October. Albany. Beef and mutton, $2\frac{3}{4}$ $\frac{4}{16}$d.; butter. $8\frac{1}{4}$ $\frac{12}{16}$d.; wheat, 5s. $9\frac{3}{4}$d.

1794, November. New England. Beef and mutton, $3\frac{1}{2}$d.; butter, from $8\frac{1}{4}$d. to $10\frac{1}{2}$d.; wheat 6s. 9d.; a drove of lean cattle going into Pennsylvania to be fed, some of which cost £18 a pair; and when fat would weigh 1500 lbs. or upwards, hide and tallow included.

About Chesterfield and Massachusetts, the best sheep in the United States, weigh as high as 20 lbs. per quarter, fleeces as 7 lbs. each, long wool but coarse, used for combing, sells for 2s. 3d. per lb. In Rhode Island, extremely fine wool fleece, from $1\frac{3}{4}$ lbs. to 2 lbs. sells for 1s. $1\frac{1}{2}$d. per lb. unwashed; hay, £1 10s. per ton.

Boston. Beef and mutton, $4\frac{1}{2}$d. per lb.; butter, 1s.; butter in barrels, from $8\frac{1}{4}$d. to $9\frac{3}{4}$d.; used to be 3d. and $3\frac{3}{4}$d.; geese, 2s. to 2s 3d.; turkies and fowls $4\frac{1}{2}$d. per lb. ready for the spit. Cattle for the *curing-houses* in all parts of New England, in the drove, calculated at 18s. 9d. per hundred lb.: hide and tallow included. Beef from 31s. 6d. to 45s per barrel of two hundred pounds nett each, according to quality; the first is very bad, the last excellent; the demand is far greater than the supply, pork per barrel, not surpassed by any in the world, 72s. to 76s.

1794, December. New York City. Wheat, 7s. 10 $\frac{1}{2}$d.

Philadelphia. Beef $4\frac{3}{4}$ $\frac{1}{5}$d. to 7 $\frac{4}{5}$d.; mutton and veal, $3\frac{1}{2}$ $\frac{2}{5}$d. to $5\frac{1}{4}$ $\frac{3}{5}$.; best flour, 38s. 3d. per barrel, of 1 cwt. 3 quarters nett; wheat 8s. $4\frac{3}{4}$d.: best timothy hay, £3 12s. per ton; maize, 2s. $8\frac{1}{4}$ $\frac{2}{5}$d. butter 9d. to $10\frac{3}{4}$ $\frac{1}{5}$d.; milk, $4\frac{3}{4}$ $\frac{1}{5}$d. per quart; bread of superfine inspected flour, 1 lb. 7 oz. for $3\frac{1}{2}$ $\frac{2}{5}$d.; of inspected common, 1lb. 8oz. for ditto; of inspected rye, 2 lbs. 3 oz. for ditto.

1795, January. Common meadow hay, £3 per ton; best timothy, £4 10s.

March. Wheat 9s.; flour, 47s. 3d. per barrel; fowls, 3s. to 4s. 6d.; ducks, 5s. $8\frac{3}{4}$d.; butter, from $10\frac{1}{4}$ $\frac{1}{5}$d. to 1s. $1\frac{1}{4}$d.

Prices current at Trenton, the depot for Philadelphia; wheat. 9s.; rye, 4s. $9\frac{1}{2}$ $\frac{2}{5}$d.; maize, 3s.; oats, 1s. $9\frac{1}{2}$ $\frac{2}{5}$d.; buckwheat, 2s. $8\frac{1}{4}$ $\frac{3}{5}$d.; ditto meal, 4s. $9\frac{1}{2}$ $\frac{3}{5}$d. per hundred lb.

May. Virginia, most part of the state. Beef, 2d.; mutton, $2\frac{1}{2}$d.; wheat, (east of the Blue Ridge) 6s. 9d.; flour, 36s. per barrel: maize, 1s. $8\frac{1}{4}$d. per bushel; wheat (west of the Blue Ridge,) 4s. $1\frac{1}{2}$d.; flour. 25s. $1\frac{1}{2}$d. per barrel: rye, 3s. $4\frac{1}{2}$d.; maize, 2s. $7\frac{1}{2}$d. Richmond. Beef. $4\frac{1}{2}$d.; mutton, 6d.; veal, $8\frac{1}{4}$d.; lamb, 5s. 3d. per quarter; wheat, 7s. 6d.; flour, 42s. 9d. per barrel.

June. Maryland, Baltimore. Beef, mutton, and veal, according to quality, from $5\frac{1}{4}$ $\frac{3}{5}$d. to 7 $\frac{1}{5}$d.; butter, 1s. $2\frac{1}{4}$ $\frac{3}{5}$d. to 1s. $4\frac{3}{4}$ $\frac{1}{5}$d.; wheat, 9s.; flour, 49s. 6d. per barrel.

July. Philadelphia. Wheat 10s. $2\frac{1}{4}$ $\frac{3}{5}$d.

New Jersey. Mutton and veal, $3\frac{1}{2}$ $\frac{2}{5}$d.; beef scarce at this season; butter, $11\frac{1}{2}$d.

New York City. Beef and mutton, $6\frac{3}{4}$d. and $7\frac{3}{4}$ $\frac{3}{16}$d.; veal somewhat cheaper; butter $11\frac{1}{4}$d. and 1s. $0\frac{1}{4}$ $\frac{4}{16}$d.; wheat, 9s. 10d.

From the above detail of prices, it will not only be evident, that the demand for exportation must be greater than the supply; but that the consumption of the great towns, affords a price more than sufficient for all the articles that are carried to them. A very large proportion of the supply, both for exportation, and the consumption of the large towns, is brought from very great distances: cattle from the Chinessee country on lake Ontario, and from Kentucky, into the neighborhood of Philadelphia; the former not less than six hundred miles, the latter about seven or eight hundred. The chief part of the flour comes in barrels, from the heads of the rivers that fall into the Atlantic; and some by land carrige, from the neighborhood of Fort Pitt to Philadelphia, a distance of three hundred miles. That a supply in itself moderate, when compared with the vast extent of country, should be collected from such great distances, is sufficient proof that the large towns have not beneficial effect on, or power to remedy, the bad cultivation of the country, even in their own vicinity.

"It is said that all the better soils in the central states, when exhausted and left, cover themselves with white clover; ascertain the fact; and observe what soils they are, upon which this fact occurs most."

In every part of America, from New Hampshire to Carolina, from the sea to the mountains, the land, whether calcareous or argillaceous, whether wet or dry, whether worn out or retaining its original fertility, from the summit of the Allegany ridge to the sandy plains of Virginia, is spontaneously covered with white clover, growing frequently with a luxuriance and perfection that art can rarely equal in Europe. In the northern States, it affords an herbage throughout the year; in the southern, the seed ripens about July; after which time the heat of the sun scorches it up, and I believe it is no more seen till the spring following. The climate or soil, or both, seem particularly favorable to this genus of plants; the *trifolium repens, pratense, arvense, alpestre*, are abundant, and several others are to be met with. It is probably too late now to ascertain whether white clover be a native of this, as well as the old continent.

I am told it is never met with far back in the woods, but immediately on their being cleared away, either by fire or otherwise, it takes possession of the ground; which should prove that it was natural to it; that the seed lies there, but cannot vegetate till the ground is cleared: but again I have been told, that by some tribes of Indians it is called white man's foot grass; from an idea, that wherever he has trodden, it grows; which should prove at least, that it had not been known in the country longer than the white man.

"Timothy produces immense crops in America: would it not be worth while to try some of the seed in England, and to sow it on the same kind of soil?"

Timothy grass* is extensively cultivated in the middle and northern states of the American Union, and I apprehend it to be the same as the *phleum pratense*, cat's-tail grass, of European botanists. I have frequently seen extraordinary crops of it, growing thick as it could stand on the ground, 3 or 4 feet in height, and in some instances coarse as wheat straw, however, in this state, as it is cut before maturity, and as in the climate of America hay is always well cured, however succulent at the time of cutting, horses prefer it to every other kind of hay, and thrive better upon it. I cannot therefore but think it worthy of some fair experiments in this country. No other grass approches it in produce; and it is particularly useful when mixed with red clover, in preventing it from falling too close to the ground.

"Clover seed from America ought to be tried, particularly on ground that is tired of English or Dutch clover seed: can such be procured?"

Clover, growing with such remarkable luxuriance as that in America, must produce good seed, and such may prove an useful change. Seed has frequently been sent from America to England; probably will be sent in future without any particular demand; and will hereafter be certainly sent, whenever ordered or required here. The price at New York in the autumn of 1794, was about 7d. per lb.

"Might not Great Britain be supplied with hemp from America?"

No supply of hemp can be drawn from the United States, since the quantity grown there is very inconsiderable, near the whole of their consumption being imported from the Baltic. No country seems better calculated for hemp than the states, as far south as the southern boundary of Virginia; beyond that, the climate is too hot for it: every where to the north of this, in every waste spot, hemp grows spontaneously, with a luxuriance I never met with elsewhere: I have seen single plants upwards of ten feet in height, with branches in every direction four or five feet in length, and with a stem more than four inches in circumference. I do not mention this kind of growth as an excellence in the hemp, because such branching would be injurious to it, but to show how congenial the climate and soil is to the plant: such excess of vegetation would be prevented in cultivation, by the closer growth of the plants.

Kalm, in his travels in America, remarks the luxuriant growth of wild hemp, particularly about the remains of Fort Saratoga, (by which I suppose he meant Fort Hardie, formerly built by the French at Saratoga;) at that very place, upwards of forty years* afterwards, I saw hemp at least eight feet in height growing wild, which probably had annually shaken its seed, and annually grown from that time to the present.

Notwithstanding this natural inclination in the soil to produce hemp, next to none is cultivated; this probably arises more from the indolence of the people, than any other cause. Hemp affords much labor in the winter, on which account it would be particularly valuable to an industrious people; but here, particularly the reverse. Winter is the season of frolic and dissipation, with which nothing must interfere. These habits do not appear likely soon to be eradicated, and till that change takes place, no hemp will be cultivated. American hemp is said to be peculiarly soft, silky, and pliable; and therefore better adapted than any other, for the running rigging of ships, and it is used for that purpose in most American vessels.

Hemp is said to be much improved in its brightness and silky quality, by being rated [rotted] in brackish water, which is always the case in America when possible: experiments of that nature, might in many instances be tried in this country.

While the United States were under the dominion of Great Britain, bounties were offered for the raising and exporting of hemp, but I believe with little effect; and are at this time continued by the state of Massachusetts, but with so little tendency to increase the culture, that the bounty for not more than one hundred tons, has been claimed in a year.

"Might not immense quantities of oil-cake for manure, and the feeding of cattle, be got from America?"

The only oil-cake† used for manure is the resi-

---

* (1799.) I have cultivated the American Timothy grass, and English cat's-tail grass, in my garden for three years; and I find not the least difference between them, except that the timothy is about a fortnight earlier than the cat's-tail; the effect of the change of seed and climate. They are the *phleum pratense* of the variety g. *nodosum* of Withering. This variety, I find, is not well founded, as the bulbous root is acquired both in the timothy and cat's-tail, by luxuriant growth; and the bulbs or knots on the roots become larger and more numerous by age; young plants, and those stinted in their growth by a poor soil, have them not. The bulbous cat's-tail, is not common in meadows, at least in this part of England; but where found, is in patches in most rich ground, and is always productive of an heavier crop than any other part of the field: and I do not find but that cattle eat that part, as close as any other. This grass appears to thrive in the garden; but should it grow when cultivated in the field with American luxuriance, I should doubt of an English sun being able to cure the hay to American perfection.

* Not having Kalm's Travels by me to refer to, I do not know the precise date.

† (1799.) In consequence of the above recommendation, the importation of oil-cake was allowed by 36 G. III. chap. cxiii. entitled, "An Act for allowing the importation of arrow root, from the British plantations, and also of linseed cakes and rape cakes, from any foreign country, British built ships, owned, navigated, and registered according to law, without payment of duty." But this act has had no effect as far as relates to the importation of linseed cakes and rape cakes from America; probably from a mistake in the wording of the act, which confines the importation to British ships alone. To import arrow root, the produce of the British plantations, it is requisite, according to the navigation laws, that it should be imported in British built

duum of rape seed, after the oil has been expressed; but as rape is a plant unknown in any part of America, though without doubt it might be cultivated there to great advantage, no oil-cake for manure can be procured from thence.

Much linseed oil is used in the United States, where the houses, mostly built of wood, are painted on the outside.

A great quantity therefore of what is called linseed cake, or oil-cake, being the remainder of the linseed after the oil is pressed out, might be purchased there; and would be highly useful in England, in fattening of cattle, and for other purposes: it is chiefly consumed there by milk-cows, in the neighborhood of the great towns, and sometimes in fattening cattle and hogs. The present price of it in America is 40s. per ton; while the price of the cake here is not less at this time than £8 8s.

A gentleman in this country, aware of the advantage of importing this article from America, was lately desirous of accomplishing it; but on making the necessary enquiries, found that those cakes came under the description of one of the *non enumerated articles*, and consequently were liable to a duty, (I believe £27 10s. per cent. on their value,) which amounted to an absolute prohibition. This prohibition seems in good policy proper to be taken off; and I cannot do less than recommend the subject to the consideration of the board.

"Irrigation is much practised; the method, soils, effect, and every other circumstance, should be attended to."

Irrigation, as far as I could learn, is known only in two parts of the United States, and in neither of them practised to any considerable extent. It offers no material circumstances worthy of imitation, nor is it conducted on any principles, that are not at this time much better understood in this country. Connecticut is the most northern state where it is met with: the practice was probably carried thither by the first settlers, most of whom emigrated from those counties in the west of England, where it is now best understood; but they do not appear to have kept pace in improvement with their kindred on this side of the Atlantic.

The German tract in Pennsylvania, is the other part where it is practised, and the knowledge was carried thither from Flanders or Germany. Two crops of hay are always cut where lands are thus artificially watered.

The law has ordained the right of the water to be in him who possesses the spring head, or the highest part of the stream; he may consume what quantity he pleases, but must convey the remainder into the ancient channel; he must not divert the stream, or waste the water to the prejudice of those below him. The mode of applying the water is different in the two states: in Connecticut it is turned on the land as soon as the weather begins to be warm in the spring; but it is not allowed to flow for more than twenty-four hours at a time: it is then taken off for a few days, then turned on again for twenty-four hours, and so on, till the meadow is nearly fit for cutting; immediately after which, it is applied again in like manner for a second crop, and then again to force the aftergrass in autumn but it is always found to have the greatest effect upon the spring crop.

In this state they also apply water to their lands, in another very different and unusual manner; they flood great tracts of low meadows, situated on running waters, just before the winter sets in, to the depth of two or three feet, by stopping the course of the stream, and let them thus remain covered till the spring, in order to keep them warm, and defend them from the frosts. These lands produce the following year a considerable quantity of coarse hay; which, in consequence of the fine climate in summer being very well got, is eagerly consumed by the cattle in winter; after the hay is cut, these fields for the remainder of the year are pastured.

In Pennsylvania the water is usually turned on the meadows about the middle of April, and is allowed to flow about two months; a few days after which, the ground having got dry, the crop is cut: as soon as the crop is off, the water is again turned on for three or four weeks, or till the land gets a sufficient covering to defend itself from the sun, at that season very powerful; a second crop is then soon ready for the scythe; after which the water is allowed again to flow over it, till within a short time before it is wanted for pasturage, when it is turned off, in order that the ground may so harden as not to receive injury from the treading of cattle. Which of the two methods of applying the water may be most productive, I know not, not having seen the meadows of Connecticut in the summer season; but those of Pennsylvania bear abundant crops.

Water issuing from limestone in Pennsylvania, is thought preferable to any other running stream; but the warm half putrid water from the reservoir made for this purpose, which is not unfrequent, or a mill dam, in which it becomes soft, slimy, and muddy, is greatly preferred to all others; water of this kind, at this season of the year, will in Pennsylvania be heated as high as 85° by Farenheit's thermometer, and must have a great effect in forcing vegetation

No art is used in conveying the water beyond a channel, carried on a level as far as it can be done conveniently, over one side of which it can flow: no means have been taken for raising it above its natural level, which in many places might be performed with much facility.

Since the introduction of clover, these meadows are falling fast into disuse, many of them having been already ploughed up and converted into tillage; no farther improvements are therefore hereafter to be looked for in this branch of rural economy.

"To examine how far, to what cause owing, and the effects of an indigent poor in the United States, is an object of great political importance, and whether such are ready to emigrate to, or beyond the mountains?"

There are no indigent poor in the United States. In a country, where in every part the demand for labor greatly exceeds the supply, where wages are high, and provisions not in proportion to them, no

---

ships; but the oil-cakes, being the produce of foreign countries, ought agreeable to the same navigation laws, to be allowed to be imported in the vessels of the country that produces them, as well as in British vessels; as all other importable articles, the produce of such countries, are allowed to be imported: no doubt the words, British built ships, where they refer to linseed cakes, and rape cakes, have been inadvertently inserted. I must therefore again recommend this article to the consideration of the board, as the importation of linseed and rape cakes, appears an object well worth their consideration.

one can want, that will labor; and the able, who refuse to work, will there meet with no support. In the country, I never heard of poor; in the great towns, there is a reception for such as want it; in which are a few people, chiefly negroes and foreigners, whom the accidents to which the lower classes are liable in a town, or the diseases of a new climate, compel here to seek a refuge. These poorhouses are either maintained by a tax on the inhabitants, or more generally by the corporation of the town, or by the state.

None emigrate to the frontiers beyond the mountains, except culprits, or savage back-wood's men, chiefly of Irish descent. This line of frontier-men, a race possessing all the vices of civilized and savage life, without the virtues of either; affording the singular spectacle of a race, seeking, and voluntarily sinking into barbarism, out of a state of civilized life; the outcasts of the world, and the disgrace of it; are to be met with, on the western frontiers from Pennsylvania, inclusive to the farthest south.

GREAT DEPTH OF THE BED OF MARL LYING UNDER NORFOLK.

Having recently learned in a conversation with an intelligent gentleman of Norfolk, Va. that the boring for water in that town had passed through a bed of marl for more than 70 feet, without reaching its bottom, we were anxious to ascertain the strength of the body: and requested to be furnished with specimens (which had been preserved) from the upper, middle, and lowest part. These have been received, enclosed in the following letter, which, though private, we will make free to publish, as it states what is desirable to know, both clearly and concisely. The three specimens were so small that no larger trials could be made than are stated below—and nothing was sought but the carbonate of lime, which is contained in very small and yet very regular proportions, for such great difference of depths. The earth when mixed with diluted muriatic acid, is of an unusually vivid green color—and probably contains more *green sand*, than of carbonate of lime. This however is merely loose supposition. The depth at which this great bed of marl lies, and its small amount of calcareous matter, render the facts of less importance to agricultural, than they may be to geological investigators.

The carbonate of lime found was as follows.

At 70 feet deep—20 grs. contained	2 of carb. of lime.	
102	34	$3\frac{1}{2}$
140	27	3

Or proportions varying between 10 and 11 per cent.

Norfolk, July 18*th*, 1835.

Dear Sir—It affords me much pleasure to be able to comply with my promise, as regards the marl found in boring for water in this place.

I have seen one of the gentlemen who conducted the operation, and have obtained from him some information as to the different strata through which the auger passed, which I submit.

"For 14 feet below the surface, fine sand.
— 16 feet more, marsh mud and shells, chiefly clam and oyster.
— 10 feet more, unable to judge—the pipe being filled by upper mud.
12 feet more, fine quick sand, unmixed.
12 to 16 feet more, a different stratum of gravel, in size from less than an eighth, to three-quarters of an inch, the longest diameter—varying in color, but chiefly clear white, much resembling crystal.

Thence to the depth when the auger broke, say 70 or 80 feet, green marl."

This information is not given from notes, and is not exact as to distances, making the depth 138 to 148—the true depth reached being 143 feet.

I have received 12 samples of the following depths: 43 feet—47—49—57—62. These five are all of sand and shells, or pure sand. The others are 70 feet—82—92—102—108—128—140. These are all of marl, of nearly the same uniform appearance as to color, and of the consistence of putty. The only perceptible difference was that the upper part of the bed seemed to have more undecomposed shell in it, although shells were found at every depth.

I enclose small quantities of the marl at 70—102—and 140 feet. Should you wish others I can supply you with them at any time.

———— ————.

THE THREE-SHIFT SYSTEM.—ON SPAYING HEIFERS.

To the Editor of the Farmers' Register.

White Marsh, Gloucester, July 10, 1835.

If I had leisure and the ability to convey my thoughts clearly and forcibly, I should certainly make some remarks for publication (and you are at liberty to use these if you think proper, and will take the trouble to correct and improve, holding me responsible for the facts*—) upon Mr. John A. Selden's communication in the first No. of the third volume of the Register; because it is calculated, I think, from the high standing and character of the author, as a gentleman and agriculturist, to mislead most farmers of the salt water region. His system may answer very well at Westover, and upon the fine wheat and clover lands on James River, after leaving the salt water, but as far as my observation extends, I do not think it will answer below. I have uniformly observed that the most successful farmers with us, those who live best, and accumulate most, (and I go for results altogether,) have been large Indian corn makers. That is a very certain crop on tide-water, whereas wheat is a very uncertain, at any rate a very unproductive one. On the White Marsh estate, producing from seventeen to eighteen hundred barrels of corn annually, it has not varied five per cent. for the last four years. There has been some improvement in the cultivation, which has enabled me to reserve a part of the former corn land for fallow and improvement, during summer, and still make about the same quantity of corn, as communicated to you in the early part of your useful publication.

I suppose Mr. Selden has stated the average corn crop made, and not what was sold, (I entertain the opinion of an old friend who considered

*We take this liberty whenever it is deemed necessary, as to matters of mere form. In this case it is in no respect called for. Ed.

the bill of lading as the best evidence of what was *made*,) by which it appears, the corn made on his estate would produce little more than one-third of the wheat made, whereas my corn crop would sell for about double the wheat and barley, (taking his price for corn and wheat, and the real price at which the barley was sold.) This year the disproportion would be much greater in favor of the corn, which clearly shows the difference in our situations, and the propriety of yielding to circumstances.

Mr. Selden informs us that he keeps twelve mules, and makes an average crop of four hundred and thirty-five barrels of corn. My regular plough team consists of six mules and six horses: two extra horses are kept, and another plough used at busy seasons. The average crop for the last four years, as before stated, is from seventeen to eighteen hundred barrels of corn. Mr. Selden complains that none of the advocates of the three-shift system will descend to particulars, and I consider myself decidedly one of them with a little variation, in having standing pastures and reserving a part of each shift in succession for fallow and improvement during summer. My three divisions consist each of about three hundred acres of low grounds, and a high land lot of about twenty-five acres, of which a part is for fallow, and that being in the corn fields is not grazed at all. From two hundred and seventy-five to eighty acres being in corn, the average product of course is a little above six barrels per acre. One of Mr. Selden's objections to the corn crop, "that it will not answer as a sale crop for persons living at a distance from navigation," is a strong recommendation to us upon the sea board. My small grain crop (that is, wheat and barley,) has averaged for the last four years about three thousand five hundred bushels per annum. The latter crop has been very unproductive for some years past, and on that account has been generally abandoned. About two hundred acres of corn land, and about sixty-five acres of fallow, are seeded in barley and wheat, the average of course about thirteen bushels per acre. I seed sixty to seventy acres of the corn land in oats, but not for sale, or very few. They are fed in a chopped state throughout the year, to every thing of the horse kind, mixed with a little meal. I have no doubt that much of the level tide-water country should be cultivated in two shifts, one year in corn, and the next in oats. A very improving bean under that system succeeds the oats, which is not the case under any other.

The most objectionable part of Mr. Selden's communication, in my estimation, is the reflection cast upon that valuable animal the ox, without whose services I would abandon agricultural pursuits. I am as devotedly attached to that species as we generally are in Virginia to that of the horse. The labor performed by oxen, when well taken care of, is incalculable; and the patience with which it is borne, always excites much feeling with me in their behalf. Nothing is consumed by them that can readily be sold from the estate. I would not permit half the quantity of corn necessary to keep them in good order to be given to mine, if it was furnished gratis; and never feed with it. A small quantity only serves to destroy their relish for coarse strong food. I would as soon think of feeding laborers on mince pies, and expect them to be satisfied afterwards with pork and bacon.

For Mr. Selden's favorite fallow system, the ox is admirably calculated. Four good oxen with one of Davis's large bar-share ploughs will execute more, and better work than any team of mules I have ever seen. When broken to, and kept exclusively for the plough, they walk nearly as fast as mules, and by working half the day and changing, lose no time to feed, and will keep in good order on the very land they are fallowing: for it either has, or ought to have, to justify the fallow, a good cover upon it. I am not a very nice calculator upon this or any other subject, but when we consider the first cost of a good mule, or work horse, the annual expense to keep him properly, the difference in gear, the interest upon the cost, and that the capital itself is lost upon an average in ten or twelve years, and then contrast him with the ox, we must decide in favor of the latter.

The mule is recommended by Mr. Selden on account of his longevity: but the ox may be said to live forever. If taken care of, an old ox will more than purchase a young one. I keep employed the greater part of the year, upon an average, thirty oxen (including spayed heifers, which my people prefer to the ox, as more active, and of better wind, and they are greatly preferable for the table.) They cost me nothing, and return to the land at least as much as they take from it.

It is so important to separate the young from the old cattle (until they are three years old at least,) without which you cannot get the females at any rate of good size, that I keep three standing pastures, one extending to the river for the purpose of salting all the stock occasionally. Another consists of an extensive wood with a small portion of open land, and is useful in winter and spring, particularly for sheep, which are very injurious to pasture early in the spring. I never graze the cultivated land until late in June—(August would be much better—) when it is well covered, and the stock can make very little impression upon it.

I am sure the annual profit by sale, derived from my stock, in addition to the supply of my family, would more than pay every expense of the estate, and almost entirely from Mr. Selden's despised race, (the sale of oxen, milch cows and butter,) for I give to my people in addition to a moderate quantity of beef and mutton, all the pork we can raise over and above the consumption of the family. I made the arrangement as an inducement to take care of and increase the quantity, and find it succeeds very well. The hams which we do not use, (more than half) are sold at a high price, and the proceeds invested in midlings, which are preferred. All the wool, with enough cotton both for the summer and winter clothing of the slaves, is manufactured on the estate, so that if we do not sell much, we purchase little.

JOHN TABB.

P. S. Since writing the above, the No. of the Register for July, has been sent me from Norfolk, in which I observe a communication on the subject of spayed cows. I have often thought it strange the practice of spaying was not more common. About sixteen years ago, my father, Philip Tabb of this county, who was in the habit of spaying two or three heifers every year for beef, at the proper age, had the experiment made on a cow with her first calf, which succeeded; and he sent her to me at Norfolk, after keeping her a year or two, thinking she would be desirable for a town cow. She gave as much milk as ordinary cows, and I thought at first she would be a great acquisition, but soon found one inconvenience attending her which had not occurred to me. Having no calf to attach and accustom her to my lot, it was necessary to send after her whenever required, or keep her up altogether, which was inconvenient, and being (as most spayed animals generally are) in fine order, I lost her in a few months, and have no doubt she was sold to the butcher. I have always regretted the loss, not so much on account of the value, but that I might have ascertained how long, and in what quantity she would have continued to give milk. I have now on this estate eighteen spayed heifers, (and I kill two or three every year for beef,) from one to seven years old. The operation is performed when they are about a year old, say in the month of May, and with the single precaution of keeping them entirely from food or water for twenty-four to thirty-six hours before—is not attended with the least risk—is performed in the same way, and may be done by any person in the habit of spaying hogs. They go to their food immediately after, and require no attention. The operation has been imperfectly performed two or three times, and they had calves afterwards: but I have only lost one, and that in consequence of keeping it suspended a very long time, in order to teach, and indeed, to permit an inexperienced hand to operate. We select the most indifferent calves to spay, which is one way to improve the stock. You increase the size amazingly. They become as large as ordinary oxen—are easily kept—make the finest beef—and as they are not in perfection till six or seven years old, we work them after three or four, to make them gentle, and consider them superior for that purpose, to the ox.

I have had so little experience in farming, and am necessarily so much absent in the performance of other duties, that I am loath to make any communication for publication, and certainly should not, but for my knowledge of the liberal and charitable feeling amongst farmers toward each other. One of the greatest objections to landed estates in Virginia, consists in the difficulty of procuring first rate managers. The difference between good and bad management is, abundance and wealth in the one case, and want and poverty in the other. I have been very fortunate in that respect; and acknowledge myself under obligations to Mr. Anthony Smith, my manager. For industry, humanity, care and attention to the people and stock, he cannot be surpassed; and I take the liberty to suggest to every farmer who has a good manager, the propriety of selecting one or two boys of intelligence and good character, to place under him. Patriotism and self-interest should prompt them to do so, as the best mode of increasing the number of good managers, and their chance of obtaining one, and of improving the country. It is impossible for the proprietor of a large estate to attend to the details; and perfectly useless for him to read, think, and plan, unless he can procure an agent who can understand and execute.

J. T.

July 13th, 1835.

For the Farmers' Register.

REMARKABLE FECUNDITY OF A EWE.

Mr. William Nottingham, sen. has at his farm near Eastville, (Northampton, Va.) a ewe which has brought 20 lambs in 7 years and 2 months, from the first to the last yeaning; and omitting the last, the first 19 lambs were produced in less than 6 years. The following dates and numbers were copied from the written memoranda kept by Mr. Nottingham, on whom, as a man of observation and accuracy, the most entire reliance may be placed.

The ewe was yeaned in February 1827.

In February 1828, she brought	2 lambs.
February 1829,	4
November 1st, 1829,	3
(being 7 in 19 months.)	
February 7th, 1831,	3
March 10th, 1832,	3
January 18th, 1833,	2
December 31st, 1833,	2
April 13th, 1835,	1

None of these were supposed to be premature births, and as large a proportion of the lambs lived as could have been expected in ordinary flocks, from births as they usually occur. Great care was generally taken of the mother, but owing to particular occurrences, she was sometimes greatly exposed. Her four lambs were yeaned at a birth, when out in a severe snow storm, and all (I believe) died in consequence. The ewe was raised as a house lamb, and is of the common breed. She was the only ewe kept on this farm, and has been always fed abundantly. When giving milk, her udder was stated to be more like a cow's in size, than that of a sheep. But if her fecundity was caused altogether by high feeding, it would seem that the same effects may be continued in her race by like treatment. Some of the female lambs of this ewe were given to Mr. Nottingham's sons, and have been kept as breeders, with the like abundant supply of food. Of these, "one has had 4 lambs at one time, and 3 at another time—another had 4 lambs at her first and only yeaning—and a third has had 3 lambs at one yeaning." These latter facts were also furnished me in writing by Mr. Nottingham's son. I omitted asking what proportion of these were raised—and did not note down the proportion of those lost by the old ewe.

Mr. Nottingham's flock of sheep is kept on grazing land on the sea side, and the mother of this family has been the only ewe kept at his house. In addition to this peculiar situation, she had the company every year except the last, of more than one male—as several ram lambs were brought home from the sea-side pasture at shearing time, to be killed in the course of the year. Upon these facts, and his observations, Mr. N. has formed the opinion that the several lambs of each yeaning, had different sires—and that the number of males in fact determined the number of lambs. Whether this strange opinion is well founded or not, Mr. N. is so sure of it, that he has latterly more than once before the yeaning stated correctly the number of lambs that would be produced. The last time there was only one male with her.

E. R.

"A DEED WITHOUT A NAME."

To the Editor of the Farmers' Register.

Having derived much useful information from your valuable periodical, the Farmers' Register, I have thought it the duty of the whole fraternity of agriculturists to contribute each his portion of information for the benefit of the rest. Indeed, my mite would have been thrown into the general coffer before this, but for my thorough aversion to placing my proper name to any paper which possibly might get me into difficulty, or which might involve any sort of responsibility. Shall I tell you the reason? A *friend* of mine gave me a mortal aversion to its vain glorious use. Some sixteen years ago I visited Richmond, and was invited by a gentleman of that city to partake of his good cheer, and being somewhat fond of the good things of this life, I indulged as far as a reasonable man may be supposed to have done. At the winding up of the feast, my friend invited me to unite with him in a note for $10,000 at one of the banks, which he would at a proper time redeem. The request was reasonable enough—the name a mere matter of form. Besides, it was quite a creditable thing to be the endorser—aye the endorser, of such a good fellow, and one who spoke of thousands as I now do of dollars. Well! sixteen years have passed away—my friend is a bankrupt—his property made over to a favored few: and if you have any curiosity to know who the author of this paper is, on the first discount day in August, a small man, of a sorrowful countenance, wearing a broad brimmed straw hat, and riding a gray mare, may be seen on the turnpike, wending his solitary way to Richmond to renew this very note. True, it has been clipped a little, but the sum of $6450 still remains due. Can mortal man wonder at my aversion, therefore, to write my name in full on any paper? Such is my abhorrence, Mr. Editor, to any unnecessary display of the sort, that in addressing my own dear children I subscribe myself generally, simply "your father." I know them to be wise, and rely on their knowledge of the old man.

With these preliminary remarks, I shall proceed to give in my experience as a tiller of the earth. *I have marled*, Mr. Editor, God be praised, I have marled. Not to the extent of thousands, but a cool hundred or two. Now mark me. In one of my best fields, I had a gall, a washed knoll, precisely such a spot as every judicious farmer most sedulously avoids when showing his crop to his neighbors. Now, sir, one of my first operations with the precious mineral, was to apply it to this knoll, or gall. And what suppose you is the consequence? Why, sir, when a neighbor comes to see me, and a walk is proposed, I generally manage to take him by a sort of circumbendibus, around to this poor despised gall, where on this 13th of July, the corn is actually tasseling, and probably will produce six or eight barrels per acre. I could not have believed it on the testimony of others.* Mortal man would scarcely believe it. And now my good sir, when my spirits are depressed, I generally take a walk to look at the corn on the marled land. When the cashier informs me that on such a day my note falls due, I walk to the marled land. If any thing crosses me there I go, morning, noon, or night. Upon my word I begin to think marl will cure half the ills of life. My wife says it has prevented the chickens having the gapes. She declares that never had she so little trouble with the young turkeys: and in fact she verily believes the health of the children is greatly improved. All this, my dear sir, she attributes to the marl. And now, sir, I am straining every nerve to fertilize every arable acre of my farm, by its immediate application. An ox cart is generally devoted to this business: and I regret that my means will not enable me apply double the force to this beneficial purpose.

I entreat you not to regard this as an exaggerated statement. I am incapable of an untruth, or any manner of deception.

SUBSCRIBER.

*_Neither can we_—and it is presumed that our correspondent will permit others in this respect to assume what is precisely his own ground. Farther—*we would not believe our own eyes* in such a case—and if more respect could be paid to the eyes of another, it would not be to a correspondent without a name.

For the Farmers' Register.

ANALYSES OF SOILS [FROM ALABAMA] MADE BY DR. R. W. GIBBES. JULY, 1835.

Colberton Plantation of Col. F. Elmore.

1. *Black or Slue Prairie*—(from Big Slue—) 6 to 8 inches below the surface.
Vegetable matter 26 per cent.
Carbonate of lime 32 "
Silex, alumina, oxide of iron [the remainder.]

2. *Hammock Prairie*—(between House and Cedar Ridge.)
Vegetable matter 36 per cent.
Carbonate of lime 22 "
Silex, &c. &c.

3. *Open Prairie*—mahogany colored—(between Gin House and William Colbert's field.)
Vegetable matter 38 per cent.
No limestone.
Silex, &c. &c.

4. *Hog Bed Prairie*—(William Colbert's land.)
Vegetable matter 26 per cent.
Carbonate of lime 8 "
Silex, &c. &c.

Of course our amount of faith as to such effects of pure marl alone, is (like our correspondent's interest in the bank,) a quantity largely *minus*.

But though holding as nought the only agricultural fact of our unknown correspondent—and supposing that his object is to make light of those whom he may deem marl-mad farmers—his communication is freely given a place; and if for no other reason, as evidence that we are willing to bear our full share of good humored reproof, whether deserved or not. In this it is hoped that a profitable example is offered to some of our "thin-skinned" friends. Whenever our new correspondent will give his true name, or authenticated facts, he will be received with hearty welcome—(and the more so if his hand writing should be more legible—) for however well he handles his present subject, it is not altogether suited to this journal, and would not have been admitted, but for its apparent personal bearing.—ED. FARM. REG.

5. *Post Oak Prairie*—(near Goodson's.)
Vegetable matter 38 per cent.
No limestone.
Silex, &c.

6. *Moulton Plantation of Dr. J. H. Taylor. Black Slue Prairie*—(Woodland's—best.)
Vegetable matter 28 per cent.
Carbonate of lime 12 "
Silex, &c.

7. *Prairie*—(scattering last post oak) mingled with red clay.
Vegetable matter 32 per cent.
Carbonate of lime 6 "
Silex, &c.

8. *Open Prairie*—from a hill or ridge.
Vegetable matter 32 per cent.
Carbonate of lime 18 "
Silex, &c.

Chisholms.

White Open Prairie—from near surface: soil not more than 18 inches.
Vegetable matter 28 per cent.
Carbonate of lime 42 "
Silex, &c.

All the specimens except the last, taken from about 6 or 8 inches below the surface.

SOME ACCOUNT OF THE PRAIRIE SOILS OF ARKANSA.

To the Editor of the Farmers' Register.

Hempstead Ark. Ter.
June 27, 1835.

The May No. of your valueble journal being received, my attention was attracted by "Statements of the constituent parts of soils of the prairies of Alabama," and more particularly fixed by the editorial remarks soliciting information on the subject of prairies in general.

In anticipation of Mr. Featherstonhaugh's forthcoming report of his geological survey of Arkansa, (though I much fear from the rapid manner of his travelling among us, his investigations have been neither accurate nor minute,) I will endeavor to give you such an account of those in my vicinity as a sixteen years' residence among them, without any pretensions to science, enables me to do.

The prairies of Arkansa exhibit every variety of soil, surface, exposure, and degree of productiveness, when under the hand of culture. Those that border the Red River are nearly a perfect level, formed of alluvion, composed of a dark red clay and sand, a little elevated above the surrounding timbered land. They contain no remains of shells, but the soil resembles in all respects, that of the timbered alluvion adjoining.

Another description of prairies occupies elevated situations, the surface composed of a mixture of rounded smooth pebbles, oyster shells and their fragments, a pale yellow clay, and a little sand. They are broken into ridges and valleys, and rounded knobs surmounted with post oak timber.

The Mound Prairie, and those that extend for some miles around it, are found of gently swelling ridges, divided by timbered valleys. They exhibit considerable variety of soil. On some the surface is mixed with sand; others are nearly or quite destitute of it: some are a deep black; others a light gray; others again are of a yellowish brown; and the whole of them rest on a foundation at various depths from the surface, from one to six feet, of a pale blue rock, that is soft enough to cut with a knife, but hard enough for hearth stones if kept out of the weather, but which slacks and crumbles into powder on exposure. I have seen corn and cotton of the rankest growth, standing in an unmixed bed of this substance that had been thrown up from the bottom of a deep well. This rock lies in strata of from four to eight inches thick, in alternate layers of harder and softer matter, and of a darker and lighter color. The lighter colored masses have been burned into a superior quality of lime, and the deeper into good potter's ware. Oyster shells and pieces of coral are every where found upon the surface, and imbedded in the rock; as well as petrified bones, and a very heavy black substance that resembles blacksmith's cinder, and entirely volatilizes by heat, with a strong sulphureous smell.* This sulphur ore, as it is called, when exposed to the air under shelter, incrusts itself with crystals of copperas. Masses of crystalized gypsum are also sometimes found deposited in chasms of the rock penetrated in digging wells. This rock, varying but little in appearance, underlays the whole of this section of country, timbered land as well as prairie. Large trees torn up by storms, many times contain, entangled among their roots, oyster shells and their fragments, rounded smooth pebbles, red clay and sand. When the timbered lands join upon the prairie, the roots of the timber are imbedded in a stiff red clay, and elevated generally about a foot above the edge of the naked prairie, exhibiting the appearance of this superstratum having been washed away from the space occupied by the prairie. The roots of the timber however, strike some depth below the red clay, into the shelly substance beneath.

These prairies when I first saw them in 1819, were clothed with a tall fine grass, and ornamented with flowers, without any mixture of timber or shrubbery, except at long intervals, where a clump of veteran post oaks had been able to resist the annual fires. Now, a large proportion of the prairie is in cultivation; and what is left out as commons is nearly divested of its native grass, by numerous herds of domestic animals. The fire has ceased to sweep over them, and thickets of crab, thorn, persimmon, mulberry, elm, honey-locust, peccan, the different oaks, the vine rose, grape vines, rattan, green brier, and blackberry bushes, render them in most places impassable. In the oldest thickets, the more vigorous trees are already destroying those of weaker growth, which die, fall, and the fire thus furnished with nutriment, begins to thin out the underbrush, and give this recent growth the appearance of young open woods. Thus, as soon as the native grass is so much eaten out as to prevent the fire from running over the prairie, these sprouts spring up—pierce with their roots the shelly substance beneath, loosen and dissolve its texture, elevate its

*This is sulphuret of iron—also found in the Alabama prairie soils. See Essay on Cal. Man., 2d ed. p. 22.

surface, change its color, and form and accumulate a rich vegetable mould. The new lands lately cleared of these thickets, and put into cultivation, are much richer and more productive than the naked prairies formerly were, that were put in cultivation before the thickets had grown; and the prairie fields that have been many years in uninterrupted cultivation, in corn, cotton, wheat and oats, and so managed, by ploughing in all the vegetable rubbish every year, as to prevent the soil from washing, are continually improving. I know of one field of fifty acres that was at first a naked gray prairie, that has been constantly cultivated in cotton for the last ten years, that produced last year a bale of cotton to the acre. The rust in cotton has never been seen in the country. The soil of this field has become black. The black timbered land of the valleys, however, the soil of which is composed of the wash from the prairie hills, mixed with the decayed vegetation of the low grounds, is that which is the most valuable. The oldest fields show no symptom of decay, nor are they much influenced by excessive rain or drought. They have been proved to be equal to any soil in the world, in any climate, for corn, cotton and wheat. The vast extent of new wild land that remains yet to be put into cultivation, has as yet prevented us from paying any attention to improving the quality of our soils, for indeed, they are so rich by nature as to seem not to require it. The crops of last year were fully equal to any ever before produced; and those on the oldest fields were the best. For this reason, the crops of wheat, though few, and on a small scale, might vie with those of the middle states in the best seasons. We have now, at this time, had no rain to moisten even the surface of the ground since the 30th of April last, yet our corn and cotton on the low grounds are not in the least injured.

Thus have I given you a statement of facts respecting the southern portion of Arkansa, as they have come within my personal knowledge. I regret much my inability to give you a chemical analysis of the different soils, and still more the want of a proper conveyance for specimens. I want to send you, or the editor of the Farmer and Gardener, larger quantities than are proper for the mail, and I would with pleasure remit a box during next season, to any gentleman in New Orleans, whom you will name to me for the purpose.

From the sensible properties of our best prairie soil, without using chemical tests, I judge it to contain a large proportion of carbonate and sulphate of lime; a due proportion of alumine, and a small proportion of silex and iron. A strong smell of sulphur is also sometimes perceived from fresh ploughed ground in a hot day, and lumps of carbonate of magnesia I have found imbedded in a red clay.

Intelligent strangers that come among us, gaze at every thing they see with wonder and delight. They find many things new and unheard of, in the appearance and sensible properties of the soil, the vegetable productions, and the indications of minerals. They are captivated with the transparency of our atmosphere, and the rosy glow of smiling health that animates the countenances of the inhabitants.

N. D. SMITH.

ON THE ADVANTAGES TO BE DERIVED FROM THE ESTABLISHMENT OF AN AGRICULTURAL PROFESSORSHIP.

To the Editor of the Farmers' Register.

Barboursville, July 23, 1835.

SIR:

It has been a settled conviction on my mind for years, that a professorship of agriculture—a pattern farm, and such a paper as yours, united therewith, would be productive of incalculable benefit to the commonwealth. The space of a letter is too confined to admit of one-half being stated. Suffice it to say, it would elevate the science—add dignity to the pursuit—call off from encumbered vocations a portion of the mind of our citizens now lost to the community—present a rallying point for all the scattered information of the land—reduce to the test of experiment every theory plausible enough to justify it—by the same standard to prove the value of every discovery or improvement—promote economy by causing one experiment for many—a certain and rapid communication, through the state, of the results—furnish a sure means of ascertaining the nature of our climate—the quantity of rain falling in the year—the seasons when drought most generally prevails—and by consequence, furnish data to guide the husbandman in the cultivation of crops, both as to time and kind. But I must stop—for I find no end to the advantages that would result from such an establishment. Let me, however, add one more. All these things are to be done before the youth of Virginia—the future men of the commonwealth, destined eventually to influence her destiny. A portion of these, selected from every part of the state (say one to each congressional or senatorial district,) of promise, but unable, from poverty, to educate themselves, to become the adopted children of the state, would be able by alternate labor and study, alike to keep up the farm, and to improve themselves. Indeed, it is worthy of the profoundest consideration, whether every student of the University would not profit by a few hours' work daily, in the proper season. These being my views, I submit to you whether it does not behoove the tillers of the earth to make an effort to induce the legislature to attend to their neglected interests. How is this to be done? I answer, as every other sect effects every thing by conventions—to that alternative we must also resort. What say you to such a convention, to meet in Richmond the first Monday in January? Let any one who feels an interest in the object attend. Let each agricultural society in the state be represented there. If it be asked what good can come of it, the answer is, let us try it. A free communion of the intelligence of the land cannot be altogether unproductive of good fruit. Apart from what can be done by such a convention on its own means, an appeal may be made to the legislature under the weighty sanctions of their united wishes, to do something for us. If the view which I suggest is esteemed impracticable, they may incorporate an agricultural society in each congressional district, and award a small sum to each, to be distributed in premiums, after the manner of New York and other states.

But it is objected that it will cost something. Have we not as a class offered our fleece annually, without a murmur, to be appropriated to other improvements? Is it unreasonable that in turn we should require a small portion of our own to be applied to our peculiar benefit? A small portion of the interest paid annually by the University, would in a few years put our scheme completely in operation, and I verily believe after that it would be able to support itself. However, all these things might be discussed in convention, and digested in a form that would be most acceptable. And I may be permitted to add, that for once we should have a convention whose sole object would be the good of the country—a spectacle so singular in these times, that it could not fail to be as consolatory as the oasis to the weary traveller of the desert.

If you agree with me on this point, you can greatly promote the object by inviting the meeting in your journal. If I thought my name would be of any service, you would be at liberty to use it with my remarks. But I fear not. However do as you please. I have it much at heart to do something. Better heads than mine may suggest better plans, to which I will most cordially submit.

Accept assurances of my high consideration,

JAMES BARBOUR.

We concur entirely with the foregoing views and recommendations, and shall be pleased to aid them, as has before been attempted, through this journal. We are also clearly of the opinion that nothing in aid of agricultural interests, or agricultural science, is to be expected from our legislature, unless prompted and urged by the expressed wishes of their constituents: and therefore the more ready admission of the necessity, and probable advantages, of consultation among the zealous and intelligent friends of agriculture—either in the mode proposed above, or in some other. There is no individual whose voice is entitled to be heard with more respect on this matter, than our correspondent; but it is desirable that others should also present their views, both as to the objects to be sought, and the mode of seeking them. Though willing to support, and lend our efforts to further any other plan of combining our force that may be found more pleasing to the greater number of the agricultural community, we see no reason now to object to the particular plan proposed above, viz: a meeting and free conference of all the members of the agricultural interest in Virginia, who may have enough zeal to join in the effort, for the purpose of determining on what aid of government agriculture most needs, and of asking it respectfully of the legislature. In the mean time the expression of different views on this subject, and discussing the comparative merits of the different ultimate objects in view, will greatly facilitate the operations of such an *agricultural conference*—and we invite to our pages, the expression of opinion of any of those who feel interest in this important subject.

It is hoped that the several societies will take the proposal into consideration, and give it their support. In whatever manner the meeting may be constituted, there can be no sound objection to the qualifications of any individual as a member. The agricultural interest in Virginia, however overlooked and neglected by the government, is still the *national interest*—and nothing can be derived for its benefit, by the whole or by any portion of those belonging to it, which would not be as beneficial to the commonwealth, as to agriculture. Such a meeting could not do otherwise than honestly labor for the good of the country—because that would be most effectually done by supporting their own. All bodies of men may be trusted implicitly when their private interest is to be promoted by the same measure, that will support that of their country—and none ought to be trusted when these interests are separate and opposed.

A STRANGE FISH.

A sea monster has been caught somewhere in the neighborhood of Norfolk, which is thus described by the Norfolk Beacon:

"Its general outline is that of a turtle, the fins or flappers being much longer. The whole fish is covered with a shining black cuticle or outer skin, (easily removed,) with the exception of the top of the head and the spinous processes of the back, which are white, with irregular outlines, as if it had been rubbed in three places. Immediately under the skin is a bony covering, extending over the back and down the sides, ridged with seven or nine bony prominences or spines, running nearly parallel with the back bone. The head is that of a turtle, with the upper lip or bill notched, so as to form two prominent pointed teeth or tusks. The throat and inner part of the mouth is fretted with spikes about two lines thick at the base, an inch long, of a horny substance, hanging loosely, but looking towards the throat, so as to permit a ready entrance, and completely preventing regurgitation, or egress. It measured eight feet in length, and nine feet from tip to tip across the fins."

From the Hartford Patriot.

ERIE CANAL.

In consequence of the great increase of business upon the Erie Canal, the Legislature of New York, at their last session, passed an act directing the Canal Commissioners to commence the construction of a double set of lift locks, as soon as in the opinion of the Canal Board the public interest should require it, and the enlargement of the Canal itself, the dimensions of the canal and locks to be determined by the Board. On the 30th ult. the Canal Board convened at the Comptroller's office, in the city of Albany, and adopted several resolutions, among which is a resolution that the public interest *does require* the construction of a double set of lift locks and the enlargement of the Canal. It was resolved to commence the construction of the locks immediately, and the enlargement of the Canal as soon as a sufficient sum shall have been collected from the canal revenue, to discharge the Erie and Champlain Canal debt—that the width of the Canal shall be in general sixty feet on the surface of the water, giving a depth of water of six feet. Several other resolutions were adopted for the purpose of facilitating the work. The Board adjourned to hear the report of the Engineers until the 20th of October next. The time required for the completion of the locks from Albany to Syracuse is estimated at three years—and six years to complete the Canal. The enlargement it is supposed will be commenced in about one year. By this arrangement the width of the Canal will be increased twenty feet and its depth two feet. It is believed the expense of this great work will be paid out of the canal revenues by the year, 1845, which is the time fixed for the redemption of the original canal debt.

WHEAT AND CHEAT GROWING FROM THE SAME ROOT.

To the Editor of the Farmers' Register.

Pampatike, King William, June 22, 1835.

As there seemed to be a great difference of opinion sometime since in the Farmers' Register among some of the farmers with regard to chess or cheat in wheat, I think the following ought to decide the matter. My manager found this morning a bunch containing three heads of cheat and two of wheat, growing from the same root. It has always been my opinion that cheat was degenerated wheat.

THOMAS CARTER.

White Sulphur Springs, July 21, 1835.

Dear Sir—Yours of the 28th ult. has just come to hand, and I am sorry the plant alluded to was not preserved, or it would afford me pleasure to send it to you. It was found by my manager, and not taken care of. He says he has seen the same thing before.

I am, yours respectfully,

THOMAS CARTER.

Being desirous of establishing truth, and not our own particular opinions, and considering with Mr. Carter that such a fact as this, fully established, would decide the controversy, we wrote immediately after receiving his first letter, to ask that the entire plant might be submitted to such scrutiny as would leave no suspicion of a mistake. This request was dictated by no doubt of the good faith either of Mr. C. or of the person who stated to him the circumstance—but by the remembrance of a mistake of our own making. Before having formed a decided opinion on this disputed matter, we once found a bunch of wheat, then just getting into head, and of which some heads were of cheat. The fact seemed conclusive: and if the bunch had been then thrown aside, after what was deemed close examination, we probably would have been always willing to swear to its truth, and of course to the fact of the transformation. But intending to preserve the bunch as a curiosity, and for permanent evidence, it was carried to the next brook to be well washed, so as to clear the roots of all the adhering dirt. In this operation, and without applying any force, or having any expectation of such a result, the roots separated, and showed two distinct bunches, so closely interlocked that they before had seemed to be one, and to have sprung from the same seed.

MANURE ON POOR SOILS. PUBLIC IMPROVEMENTS, AND POLITICAL JOBS.

To the Editor of the Farmer's Register.

Caroline county, Va. July 27, 1835.

Your remarks on my letter, (Farmers' Register, Vol. II. page 614,) have, I have learned, disheartened many farmers on poor land, and I assure you, sir, I saw nothing in them to cheer my spirits, or increase my ardor in attempts to improve lands naturally poor. The consumptive patient does not always despair after an unfavorable prognosis. "Hope ever lingers in the hectic breast." Your experience, it seems, as well as my own, goes to prove the difficulty, if not impracticability, of enriching lands naturally poor, (and exhausted too, by long cultivation) by vegetable matter alone. You have pursued the four, and I the three-shift system. You have fortunately found a remedy in *marl:* I have not. You seem now to pursue a course calculated to make amends for all your former errors and disappointments, as well as your toils and losses. In this situation, sir, I think you seem to abandon us to our fate, if not with disgust, at least with but little or no hope for our success. Without marl or lime, we are doomed to poverty or emigration: and to add to our sufferings, your "Commentator" laughs at our calamity. This is more than we can bear. *You* are elated with your discovery of the catholicon—*he* with a smile points you to the *opprobrium medicinæ.* Whatever may be the success of your panacea, we cannot but hope that the God of nature has provided other available remedies. Do not too hastily conclude that human genius and human effort must centre in lime. Do not believe that all lands naturally poor are doomed to their present condition without lime. Would you, sir, presume that you have fathomed the depths of nature, or spanned the circle of human ingenuity? Remember the story of the three clergymen and the setting sun in St. Piere's "*Studies of Nature.*" How do you know, sir, but your discoveries (and great I must call them) are but the platform: the mighty edifice is yet to be erected. Damp not then, I beg you, human effort; nor doom not to endless poverty the descendants of poor-land-farmers in our native state.*

---

*We could not state our views more clearly than was done at the place referred to above (Vol. II. p. 614,)—and indeed, though condemning their having been so expressed, our correspondent seems to concur entirely in their general correctness. When declaring that the putrescent manures alone, furnished by a farm of soil naturally poor, could not enrich it—and that calcareous matter being added *would* serve to produce that effect, certainly and profitably—it was not thought necessary to state also (what we now readily admit) that there may be other substances or means, though as yet unknown, which may serve the same or even a better purpose than calcareous earth. We then knew of one means only, and therefore spoke of no other. We were aware that the views expressed were likely to be unpalatable to many—and certainly the expression was not calculated to aid the popularity, or add to the profits of this journal. Our correspondent

When I spoke in my letter of lands originally poor, I enclosed in a parenthesis "*I may say compared with much.*" Now if most of those lands were poor enough originally "to make a rat cry," I do not know it; whatever they may do now. I had heard of one or two generations preceding the present, with large families, some of them buried in the forests of the west, and some of them buried by the sepulchres of their progenitors. As poor then as these lands may have originally been, as poor as they now are, should they be abandoned, without more than a *single* effort being made to restore them to their pristine, or a much higher degree of fertility? Last of all, should *statesmen* and *politicians* ridicule them? Should the farmer himself? Should the agricultural chemist? Not yet having discovered a system, a remedy, ought not this very failure to excite the compassion of the statesman and the patriot? Although, sir, I consider myself but a poor politician, I had reflected a little upon the condition of the farming interest of our native state, the bone and sinew of the commonwealth. I thought I had discovered that under the present system (or rather want of system,) our state was, and had long been, on the decline. That great numbers of her most wealthy and intelligent farmers had moved to the rich lands of the west and south-west, carrying with them their wealth, and intelligence or knowledge, which is said to be power, and left only their depreciated lands—whereby the sources of taxation for the support of all state expenses were daily diminishing. In addition too, the learned professions must necessarily have a more scanty support: and I had for years seen the young lawyer, physician, and perhaps the more useful divine, wending the same way. When, in fine, I saw a rapid decline of our state, both physical and moral, I was constrained to ask the political questions, with suggestions, from which, "Commentator" with so muck kindness and confidence informs us that I "appear less at home." I hope "he will pardon me for saying," that after reading his commentary I am "of the same opinion still;" and I believe I am so, not because his views are "against my will." I feel no disposition, nor have I the information or ability to enter into discussion of this subject: yet I will say, that although I have not "consulted the most approved writers on the subject, nor statistical comparisons of the two methods of conducting internal improvements by private chartered companies, or entirely on state account," yet I should suppose after all that has been written by "the most approved writers," that there is opening for *two* opinions upon the subject, from the fact of some recent internal improvements (in other states) on the "state account" principle being in progress, or that "the most approved writers on this subject" must have very recently come to light.

As regards the trial of our sister state who has involved herself in a debt of some fifteen or twenty millions of dollars, I conceive the trial as yet by no means concluded. "Commentator" may suppose after the completion of these important works, the tolls will never be sufficient to pay the interest and necessary expenses, much less to extinguish the debt or loan. If so, the trial will be conclusive. Should the tolls not only pay the interest and expenses, and extinguish the debt, and ever after bring a handsome revenue into the state treasury, then I suppose "Commentator" would not object; even too, if many of those undertakings have been made poltical party jobs, with incompetent undertakers and superintendents, and the expenses much greater than those of any private company or companies. I say so for this reason, that where a *state* undertakes all these internal improvements, some of them might fall far short of expectation, and be unproductive, either after the strongest presumptive evidence that

---

knows well that the physician who would always honestly tell his patients when he considered their diseases past the aid of his skill, or who refused to prescribe for what he knew to be incurable maladies or infirmities, would soon lose his practice. The rule applies as well to land doctors, as to body doctors. As there are plenty of the latter who will always give their patients *hope*, even when *help* is out of the question, so the great body of prescribers for the diseases of soils always promise relief, and a state of vigorous health, and to be gained easily, cheaply, and profitably. Such flattering promises are always more impressive than statements of opposite character—and if any readers desire to get rid of all despondency produced by our former croaking, let them read the first address to an agricultural society that comes to hand—and ten to one, but they will find the proper remedy, in the prospects exhibited, of certain, speedy, and cheap agricultural improvement, on the poorest and most intractable soils.

But for our part, we cannot hold out what are believed to be delusive hopes—and we consider that the only solid expectation for a cure must be founded on the full knowledge of the malignity and strength of the disease, and of the nature of the medicines proposed to be used. We do not say to the tiller of naturally poor soil that there is no hope for fertilization or profit—but that he will fail in reaching both, if reliance is placed solely on not grazing, and otherwise applying putrescent manures.

But even if any region is so situated, that making the soil generally fertile cannot be reasonably expected, there are particular kinds of products which might be there obtained, and yield as much profit as an equal amount of capital vested in richer land elsewhere. Much of the land of New England furnishes examples of this truth. The soil is so destitute of lime, that it is not only naturally poor, but is incapable of producing wheat to any profit. Yet these lands yield great profits, and command high prices. Two of the most profitable parts of agricultural business pursued there, are silk culture and sheep raising—and both of these are much more opposed there, than here, by the long and severe winters. These are only named as examples. In Virginia, we scarcely ever think of a change of crops, products, or habits, no matter how much required by difference of soil. We almost every where aim to raise corn, wheat, oats, tobacco, or cotton, for market—and seem to have no choice except among those very few of all the numerous and varied productions of the earth, and of agricultural industry.

they would be profitable, or from incompetent undertakers and superintendents, and exceeding great expense: yet when the whole be completed, if the result be an income not only sufficient to pay off the debt and expenses, but to relieve the citizens of the commonwealth from direct taxation, what more could be wished.

The last important objection with "Commentator" is, that "almost all matters of internal improvement when undertaken on public account, are forced to subserve, in locality, in the choice of agents to conduct them, and in the expenditures lavished on them, the popularity of the occupants for the time being of political power." This I presume would be true in a greater or less degree. This, however, is one of the evils attendant upon fallen man. It may be traced to the principle of self-love, which prevents men from doing unto others, as they would that others should do unto them. As these favors depend upon the *occupants* for the time being, and the occupants depend upon *popularity*, and popularity (I am truly sorry to say it) upon the *wind*,* and the wind blows from different points in a short time, so it may not be long before these favors are pretty equally divided. At any rate I see no good reason why through fear of partizan favors, varying with the popular breeze, we should have all the control, profits and emoluments (which may be great) permanently fixed upon a few individuals and their heirs, instead of the profits being thrown into the public treasury for the common weal. When I penned the questions above alluded to "on certain topics of political economy," I had not the smallest expectation of ever hearing of them again. Yet as they have been thought so erroneous by "Commentator" as to excite his attention, and as I verily believe with a view of correcting the error; and as he has failed to convince me, I thought it but proper to state some of the reasons why I had not yet embraced his views. I assure you, sir, as I have before said, that I am no great politician. I should be unwilling to introduce the subject into your paper on party grounds, and should be sorry to see it in these days of excitement, introduced by others far before me in political acquirements. I hope so far as we have gone, we have not transcended the limits of political economy—one of the branches not improperly introduced for the general good.

If I have wandered from "home" into a wilderness, I have met with a native of our own state, (in No. 3, Farm. Reg. pp. 138, 140,) whose company cheers me in the desert; who, upon the subject of the improvement of the James and Kanawha Rivers, says: "I have no hesitation in saying it would have been better for Virginia to have borrowed the whole sum instead of raising it at home by subscription; for I have no doubt that the tolls on the improvement will ultimately pay much more than interest on the money expended, &c." Again the same writer, Professor Dew, says: "I do not, however, by the remarks made, wish to be considered as censuring those who favor the joint-stock scheme of our state. It was the only plan perhaps which could have been successfully carried through, and therefore ought certainly to have been supported rather than leave the state without any improvement at all."

T. B. A.

P. S. My remarks have run in rather a different channel from that I had intended. I wished to have speculated a little upon your theories in your work on Calcareous Manures. I wished also to ask the favor that you would collect and publish in your Register, the best information upon the use of quicklime upon different soils.

* We think that our correspondent does great injustice to the *wind* in making it the cause of such effects. The wind is honest and "straight forward"—and, whether it is doing us good or harm, we can at least always tell which way it is blowing for the time being.

From the last London edition of the "Complete Grazier."

ON THE BREEDING, REARING, AND FATTENING OF SHEEP.

[Continued from p. 222 Vol. III.]

On the treatment and rearing of house-lambs.

In the preceding chapter, the treatment of lambs intended to be kept for stock, has been chiefly regarded; but, as the price given in the winter, in the metropolis, and in other places where there is a demand for young lambs, is often very considerable, we shall, at present, confine our attention to the rearing of those animals, under cover, in which case they are denominated *house-lambs.*

In this branch of rural economy, two circumstances are worthy of notice: 1. To put the rams and ewes together at such a time, that the lambs may fall at the proper season; an object which may be easily effected by any skilful shepherd: and, 2. That appropriate places be provided for their reception. Where the suckling of house-lambs is intended to be regularly followed, it will be necessary to erect a house of such proportions as the probable extent of the business may require, and to divide the building into pens, in order that each lamb may be more conveniently suckled; but when it is not a primary object of attention, any airy building may be made to answer the purpose. Care should also be taken, not to crowd too many into one house at the same time; as the increased degree of heat, thus occasioned, will render the place unwholesome.

The breed of ewes, best calculated for producing house-lambs, is the early Dorsetshire sort, particularly those whose lambs die *fair*, in the language of the market; i e. whose flesh is of a delicately-white color: and from this prolific variety the demands of the luxurious in the metropolis are supplied. The dams are fed with hay, oil-cake, corn, cabbage, or any green food afforded by the season; which is given in an inclosure adjoining the apartment where the young lambs are confined. The light is excluded from the lambs excepting at the intervals when the shepherd suckles them upon the ewes; and some feeders confine them in separate stalls in order to prevent them from playing, and thus promoting their fatting, but others deem the exclusion of light to be sufficient.

Where the system of suckling is carried on to a great extent, it will be advisable to mark the lambs, in order to ascertain which has been longest sucking on the *bastard ewe;* (i. e. such as suckle strange lambs,) as such lambs ought to *suck a-head*, or be permitted to take the first milk. There is great difficulty in compelling the ewes to suckle strange lambs; but when they have lost their own by accident, they may be deceived by stripping the skin from the dead lamb, and stitching it round the body of a live one.

In the intervals of suckling, some wheat straw may be given to the lambs in racks, either with wheat or bruised peas in troughs, together with a piece of calcined chalk for them to lick, but as the ewe's milk is the chief support of their young, especial care must be taken to supply her with turnips; or, in case these or other roots cannot be procured, besides turning her into a good warm pasture, she should be fed with brewers' grains, to which may be added a little hay, oats, or bran; but the last mentioned articles are greatly inferior to turnips, or any of the succulent roots, in producing a flow of milk.

The ewes ought to be conducted to the lambs three or four times in the day, at nearly equidistant periods; and if any one have a more than ordinary flow of milk, she may be held by the head, while a second lamb draws the udder. During the whole of the treatment, the strictest attention ought to be paid to cleanliness; to promote which, the pens should be well littered with fresh straw; and, by this simple expedient, the animals will, if kept free from all disturbance, speedily fatten, and their flesh becomes exceedingly white and delicate. Some estimate may be formed of the profit arising from rearing house-lambs, from the prices given *per quarter* in the London markets. These, retail, vary from ten to fifteen, or twenty shillings, according to the demand, so that each lamb sells at from two to four pounds; though the prices afterwards gradually decline, till the ensuing spring affords an abundant supply for the table. Yet, whether from the great trouble of the requisite attendance, or from the precariousness of the result, it is a remarkable fact that, notwithstanding the increase of population, the rearing of house-lambs has, of late years, materially fallen off.

On the feeding of sheep.

The successful feeding of sheep must greatly depend on the quality of the pasture intended for their reception, and upon the resources which the farmer has for supplying them with food during the trying winter months. Hence, as already intimated, it will be necessary to suit them to the pasture, and on no account to purchase or procure sheep from the grounds of a superior quality to those which are destined for their support. With sheep, as with other cattle stock, it has been found that the larger breeds are calculated only for the richest and most luxuriant grounds, while the smaller sorts are best adapted for the less fertile tracts, where the grass is shorter; and as the breeds that are most beneficial for particular situations are detailed in the introductory view prefixed to this book, we deem any further remark on that subject unnecessary.

In the grazing of sheep, as well as neat cattle, various methods are practised, and with different success. Thus some farmers buy two, or three-shear wethers, early in May, which, for several weeks, are indifferently kept till all the grass has been mown off the meadows, when they are turned into the rowen, and are afterwards *forced* or fattened off on turnips, hay, and oil-cake, during the winter months, so as to be fit for sale at the commencement of march. This practice is very beneficial, if conducted with care, as mutton fetches the most advantageous prices in that month.

Others purchase pregnant ewes towards the close of summer, or early in the autumnal quarter; and keep them on inferior grass lands, stubbles, or fallow, till the beginning of the following year, when they are kept in good condition through the lambing season, and after that in the best manner that circumstances will admit: so that the lambs may be ready for sale in sufficient time for the dams to be fattened for the butcher early in autumn.

Another profitable practice on good soils is, the buying of lambs of forward breeds, about the end of August, or in the beginning of the following month. The animals thus acquired are, by some graziers, kept in an indifferent way throughout the winter, till the following spring, when they are turned into rich pasture, and fattened so as to be ready for sale before Christmas, at which time the whole stock are cleared off the land. Others however, adopt a system altogether the reverse of this: having purchased the sheep, as already stated, they force them with the best keep that can be procured, and dispose of them as quickly as possible. Each of these plans has its separate advocates; they are all good; and the preference to either can only be determined by relative circumstances of soil and situation, the quantity and the nature of the feed.

In grazing sheep, the fine grasses produced on downs are, undoubtedly, the best and most congenial food for these animals; and, on such soils, both the finest wool and the best mutton are produced; but in order to bring sheep forward at an earlier age than would be possible on such herbage, and for the larger breeds reared on lowlands, richer pasture is necessary: good hay alone will fatten wethers; but they may be yet more advantageously prepared for the butcher by means of grass and hay together. Great attention, however, is necessary, that sheep be kept from all grass that is grown in marshy places, otherwise they will become affected with the rot. And here it may not be amiss to remark, that the late Mr. Bakewell attributed this fatal disease solely to flooded lands, and the premature, but unsubstantial, herbage afforded by them. Whenever, therefore, particular lots or parcels of his sheep were thus affected, his practice was to fatten them for the butcher; and, probably from motives of jealousy, in order that he might be certain the animals would be killed, and not got into other hands, he was said to rot them before they were disposed of. This he effected by overflowing a pasture or meadow in the summer, in consequence of which the soil thus flooded inevitably rotted the sheep that were fed on it in the ensuing autumn: but this, it should be observed, does not apply to irrigated land, if properly managed.*

Beside humid situations, and the acid grass vegetating there, the tufts of long, rank grass that usually spring up after horse-dung, are injurious, unless the grass has been previously exposed to a few nights' frost, after which they may be turned

---

*See Book VIII. Chap. XI.

in without danger. It is also improper to suffer sheep to browse upon fallows that are wet and unsound, as they frequently pull up unwholesome herbs by the roots, which they eat with the dirt adhering to them. This has been thought to give them the rot; though there is much reason to doubt the accuracy of that supposition, which, indeed, is manifestly at variance with the fact, that sheep fed on turnips, with which they necessarily lick up dirt, are not thereby affected with it, though they may be injured by the weeds. The origin of the rot, so far as it has been ascertained, is solely attributable to the wetness of the land on which sheep are fed; and its immediate effect is the production of insects, termed *flukes* or *flocks*, which prey upon the liver; but whether these are generated in the animal by the nature of the food, or are derived from animalculæ absorbed with it, is still unknown. It is observable that salt marshes are exempt from this malady; and therefore salt has, not unreasonably, been conjectured to afford a preventive, but its effects have not been sufficiently tried: the best is a dry pasture. In such pastures, however, as are subject to give sheep the rot at certain times, it will be advisable to let the lambs run with the ewes; the longer the better: for though these tender animals are more susceptible of injury in these unsound places than full-grown sheep, yet they are seldom attacked with the rot, suckling having been found a preservative against it.

In turning sheep into pastures, particularly water-meadows, and also into those places that are subject to rot, it will be necessary to pursue the same precaution as with neat cattle, viz. previously to satisfy the craving of appetite, by giving them hay or cut straw; and, after the dew has been evaporated by the rays of the sun, to drive them gently round the field for two or three hours, before they are suffered to feed. But, whenever any sort of dry food is given, they ought to be supplied with pure water, particularly during the intense heat that usually prevails during the *dog-days*, and which often renders the grass as dry as stubble. For this purpose, clear, light running water is always to be preferred, where it can be obtained; though, in general, whatever water presents itself is made use of.*

The best time for turning sheep into summer pastures is in May, when every attention should be paid to proportion the number according to the luxuriance of the grass; and, as these animals are with difficulty restored to good condition when injured by want of sufficient food, it will be advisable rather to understock than to overburthen the land. It is, however, worthy of notice, that by pursuing a system of *close feeding*, the plants will be prevented from running up to seed, and those grasses, which are naturally coarse and unprofitable, will thus be kept down, and become sweet and valuable. The number to be allotted to an acre depending on the weight of the stock, the richness of the soil, and the forwardness of the pasture, it must be evident that no general rule can be applicable to this portion of management, which must be wholly regulated by the combination of those circumstances.

Of late years, it has become a frequent practice to soil sheep during summer with the various artificial grasses, and to supply them with corn, as well as green food, during winter. In this view, barley-meal, when abundant and cheap, may be advantageously combined with green meat, and will speedily fatten wethers: pulverized oil-cake has also been given; but has been objected to, as it is apt to impart a peculiar flavor to the mutton. Pea-haulm is much relished by sheep; and potatoes, particularly if steamed, would rapidly contribute to fatten them, were not the operation attended with two much trouble for the feeding of a flock. Borecole and burnet also supply an excellent food for sheep during the winter, particularly towards the close of that season; but in most situations turnips form the farmer's chief dependence for the winter-keep of his sheep-stock.

There are various methods in the use of giving turnips to sheep. By some farmers, they are promiscuously turned into a field, and allowed to eat the roots at pleasure; either previously picking these out of the ground for their use, or leaving the sheep to do that themselves. Others divide their land by hurdles, and inclose the sheep in such a space as these can clear in one day, advancing progressively through the field till it is cleared. But, in either case, care should be taken not to turn them in until the dew is off in the morning, as by their eating the turnip-tops they would be subject to become hoved. Another method is, to pull up such a quantity of turnips as they can consume in a few days, and cart them off the land to the sheep pastures; and in wet weather, or when it is an object to feed off the turnips on the ground on which they are grown, this is an advisable mode.

Each of these methods has its advantages; but a more profitable plan than either, is to eat off the crop by two successive flocks of fattening and store sheep. By allowing the first the range of the field, they will scoop out such turnips as they prefer, and will thus satisfy their appetites better than where the turnips are dug up: a most material point, it may be observed, to be considered in fattening all cattle, which should always be indulged, when that is possible, with such food as they prefer. The store sheep may then follow, and the roots and pieces left by the former should then be taken up for their use. One man with a common picker, used for the purpose, will turn out and break as many as will serve a large flock, and his hire will be more than compensated by their being eaten

* The watering of sheep is on the continent, regarded as a circumstance of the greatest moment, and accordingly receives that attention which it requires. Thus in Sweden, and at the national farm at Rambouillet, in France, they are daily watered with running water, or with that obtained from lakes and springs; stagnant water being most properly and rigorously prohibited. In some of the Saxon sheep-farms, the sheep are watered in the cots or folds during the winter, instead of taking them to watering-places. Spring or well water is conducted, by means of pipes, into troughs, out of which the sheep drink at pleasure; they in consequence drink oftener, and each time take less water, which is favorable to their health. The ordinary mode of watering sheep in that, and, we may add, in many parts of our country, is attended with many inconveniences. The animals refuse to drink water in the winter, if it be too cold; they hurry while drinking; and do not take enough when the weather is very windy, or hail, rain, or snow falls. Besides which, they often disturb the water with their feet; this disgusts them, and at length, one part of the flock completely prevents the other from approaching the watering-place.

clean up; while, if that were done by the fattening flock, it would perhaps rather check than forward their improvement. When the turnips are hurdled off to be eaten on the land, they should always be taken up; as otherwise, in so small a space, they would be trodden under and spoiled; if not taken up, the sheep should be allowed more room.

But the fattening of sheep cannot be conducted to advantage without regularity in distributing, and economy in the management of, the various articles that compose their food. Hence it will be found useful to have troughs, with partitions in the middle and racks annexed, about two feet high from the ground, the whole being firm and steady, so that it cannot be overturned.

The sheep-cribs and racks in common use, are too well known to require description. Considerable benefit may be derived from their adoption for the purpose of feeding sheep; for it not only effects a material reduction in the consumption and expense of provender, which is thus prevented from being trodden under foot, or soiled with dung; but also, in this state of separation, the stronger sheep cannot drive away the weaker, as each is secured by the head.

But whatever system of management may be adopted by the farmer, whether at home or in the field, he ought on no account to withhold salt from his sheep; for not only does the continual use of that article contribute to the digestion of succulent vegetables, and of course preserve the animals in constant health, but it is also said to improve both the quantity and the quality of the wool, and it ought to be particularly used in those moist situations, the produce of which is liable to rot sheep, of which malady it is affirmed to be both a preventive and a cure. Rock-salt is undoubtedly preferable; but, where this cannot be conveniently procured, it will be advisable to dissolve common salt in water, and after mixing it with fine, pure clay, or with pulverized and sifted chalk, to form the whole into masses or lumps, which may be placed under shelter, so that the sheep may lick it at pleasure.

The importance of salt in preserving the health of sheep is not generally known, or appreciated, by many breeders of this island, who do not give it in any form. The same prejudice exists in Prussia and Holland, where no salt is allowed to these animals.* On the contrary, at Rambouillet, in Silesia, Saxony, Sweden and Spain, salt is considered as a most important article, and the use of it is most strongly recommended. In Sweden, they give salt, particularly in rainy or damp weather, and frequently add to it wormwood, or some other bitter vegetables, juniper seeds or berries, and even pitch, which articles are reduced to powder, and, after being diluted with water, are carried to the sheep house, and put into the trunks of trees, which are excavated expressly for this purpose: the preparation is considered as an excellent preventive of several distempers, particularly the dropsy, to which the Swedish sheep are very liable. In this country, the high duty on salt has hitherto prevented its employment for many agricultural purposes, to which it might be beneficially applied; and to none more advantageously than in the feeding of cattle; but as that objection now happily, no longer exists, it is to be presumed that it will be gradually brought into use.

*In Holland, the use of alder leaves, which the sheep eat with uncommon avidity in wet weather, is said to prevent the rot.

The preceding statements have been given chiefly with reference to the fattening of sheep profitably for the market; but it ought never to be forgotten, that the growth of the wool is liable to be materially affected by the system of feeding pursued. It is essential to the evenness and strength of the staple, that the feeding of the animal should be uniform, without any sudden interruption or transition: for, where this is suffered to take place, the natural progress of the wool is checked; a second growth succeeds; and the point of contact becomes so weak as to snap under the operation of the manufacturer; who, being aware of this disadvantage, cannot of course afford such a price for wool of this description, as he could for that of a more perfect staple. Much wool is injured in this way between summer and winter keep, which should be made to blend as gradually as possible, that the mischief above described might be prevented, and a sudden transition from rich to poor diet or from poor to rich keep, ought carefully to be avoided.

[To be continued.]

From Loudon's Gardener's Magazine.

TO PRESERVE CELERY THROUGH THE WINTER.

Get up the celery on a fine dry day before it is injured by frost, cut off the leaves and roots, and lay it in a dry, airy place for a few days; then remove it to a cool cellar, where it will be quite secure from frost, and pack it up with sand, putting layers of celery and of sand alternately.

STEAM-DIGGING MACHINE.

M. Wronski, a celebrated mathematician at Paris, has, according to the Paris papers, discovered a new system of applying steam to carriages, digging machines, hoes, picks, ploughs, &c.; so superior to any thing hitherto known, that a French company has bought his patent for four millions of francs.—*Le Temps*.

From the Farmer and Gardener.

LIMING IN LEHIGH.

In speaking more particularly of Lehigh county, it may be assumed, that the introduction of the use of lime in farming, and the culture of clover about 20 years ago, wrought a most salutary revolution, and saved the second and third rate lands from being deserted for the far west. Ever since that period agriculture is rising. Every summer adds to the number of solid and capacious barns, and old ones are enlarged. A considerable part of the county, especially on the borders of the Lehigh and its tributaries, is limestone land, but the trouble and expense of carting the stones the distance of 14 miles is not thought too much, thus almost the whole of our county is provided with this commodity. As soon as winter sets in, or as often as during summer the other farm operations are suspended, the quarries present a lively scene, and wagons or sledges are seen toiling along up and down through the country, broken and hilly as it is in many parts. The consequence is, that you see beautiful farms not only in hollow lands, but in situations where you never would look for them, on the tops of the mountains as well as on their declivities. Wheat however is not the only staple article; we produce a great quantity of rye for sale and home consumption, for man and beast; for be it remembered that we eat rye bread in preference, even when we have both sorts on the table. The effect of lime upon rye land is quick and immediate, hence whoever is improving his land begins with rye. On the Lehigh land quarried limestones are sold at the quarries for 25 cents per ton. In other sections, the common way is for farmers to do all the labor themselves and pay to the owner of the quarry 6 cents for every ten bushels of quicklime they draw from the kiln, or they engage hands paying to them from 1 to 1½ cents per bushel of quicklime, the hands to find their own tools and powder where necessary—this is in addition to the fees of the owner of the quarry. The work at the kiln to be done by the farmers. If you wish to buy quicklime you can have it deposited on the fields at ten cents per bushel and upwards, according to distances. We put from 40 to 60 bushels on the acre, repeating the operation every five years. From the time that stone coal from Mauch Chunk has been furnished in abundance along the Lehigh canal, and that its use in burning lime has been understood, agriculture has received a new start. Previously, the scarcity of fuel—though rather prospective than actual, operated as a check upon the universal use of lime. Now the coal is mixed with the lime stones, and no more wood is required but what is necessary to ignite the coal, which may be done with 1 or 1½ cords, thus not only a mass of fuel is saved, but a great deal of hard labor—the coal when once fairly burning requiring no farther attendance.

Timothy is not much raised on dry land, as its effect upon the land is not so beneficial as that of clover. Common rotation, 1st. clover, 2d Indian corn, 3d oats or flax; and potatoes, manure, 4th wheat, 5th and 6th clover, 7th wheat, without manure; 20 bushels of wheat—50 bushels of Indian corn, 2 tons of clover per acre, are good crops, though there are many instances of more having been produced. Average somewhat below this.

For the benefit of such as wish to sprout a few seeds of gama grass, let me add my recipe. Split the seed with a small chisel, put the kernel in a tumbler with sand, keep it moist, and in 3 days, if the seeds are not covered too deeply, the grass appears. The splitting is easily done. The seed of gama grass is in the shape of a cylinder, on the surface of which you will observe a spheric triangle, two sides being formed by seams, and the third by the base of the seed, but the two sides or seams, one not quite connected with the base, make the connection with the chisel or knife, and the triangle will fall out like a trap door, the kernel adhering to it; take care not to separate it further, or injure it, which is very easy to avoid.

From the Tennessee Farmer.

TO DESTROY BRIERS.

We are assured by a respectable and intelligent farmer, that from the repeated experiments of himself and his neighbors, he is able to state with confidence that briers, both the blackberry and dewberry, will be effectually destroyed by cutting them down or ploughing them up when they are in full bloom, which is ordinarily in the month of May.

From the Tennessee Farmer.

SAVING CLOVER SEED.

Answer to Queries of a subscriber published in the Farmer No. 6 page 91.

The two great objects to be attended to, in raising clover seed with profit, are—first, to secure the production of as large a crop to the acre as practicable—and secondly, to harvest the crop in such a manner, as to bring as large a portion of the seed into the barn and to leave as small a portion of it as possible in the field.

To attain the first object, that of securing a large product, we have in our preceding numbers, in observations on the culture of clover, given the necessary directions; we will now only repeat, that the main things to be attended to are the following—1st. That the land be fertile. 2d. That it be well prepared before sowing the seed, as heretofore directed. 3d. That a sufficient quantity of seed be sown to the acre. 4th. That it be evenly distributed over the ground. 5th. That, whenever the land requires its aid, gypsum or plaster be sown on the clover—and 6th. That it be not injured by injudicious or excessive grazing. If these particulars be well attended to, an acre of ordinary land will produce three bushels of seed in a common season, often more.

We come now to speak of the more difficult and laborious operation of safely and economically harvesting and securing it. This requires care and attention. The great objects to be aimed at are, to cut the seed at the period when there is the largest portion of the ripe seed on the ground, in that stage of maturity, which will admit of its being collected into the barn, and so to handle it, as to prevent the seed from being shattered off and left on the field, while the straw or haulm only is collected in the barn. It is, we believe to the improvident and ruinous neglect of strict attention to these two latter objects, that most farmers may attribute their failure in making clover seed. We will lay before our readers the results of our own observation and experience, on these important points, hoping that those of our patrons, who may have discovered a better mode of effecting these objects, than the one recommended, will yet communicate to us their practice in time to enable us to lay it before the public in our next number.

Time of cutting.

As the clover seed, from the time the first heads ripen, until the close of the season, are daily arriving at maturity, the great desideratum is, to ascertain the precise period when there is on the ground the greatest portion of ripe seed, in a state which will admit of its being collected and brought into the barn. If the clover be cut before this period, there must evidently be a loss sustained, from the immaturity of too large a portion of the seed. If the cutting be deferred beyond this period, an equal, and perhaps a greater loss will be sustained, from the impossibility of saving the seed first ripened, generally the best, on account of its being so easily shattered off. We would recommend, as the most eligible time for cutting, the period when about two-thirds of the heads have become ripe and assumed a black color, many of the others, at this time of a brown color, will ripen after cutting.

Mode of cutting.

Where the clover has not lodged, and is high enough to admit of it, by far the most expeditious, and in every point of view the most eligible mode of cutting, is to cradle it as we do grain, only throwing it into double swarths, that is laying the clover cut from two lands in one swarth. If the grass be so short as to require it, a strip of linen may be fastened on the fingers of the cradle so as to prevent the heads falling through them.

Mode of curing.

If the crop be not heavy and the weather be good, the swarths may lie undisturbed for several days, until the hay be perfectly cured, it should then, in the morning or evening while sufficiently moist from the dew, to prevent its shattering off too easily, be gently raked into small bunches, such as can be conveniently raised with a fork and laid on the wagon. When not too damp, these bunches should be hauled to the barn, and either stowed away in mows, or, which is best, thrashed off, and either immediately cleaned, or else the heads stowed away in a room prepared for the purpose until winter, to be then thrashed or trodden out. But should there be rain on them, or should they be suffered to remain in the field any considerable length of time after being raked up, these bunches must with a fork be gently turned bottom upwards, and laid in a new place, after every rain to which they may be exposed, and after every two or three days they may have lain in the field in fair weather. This is necessary to prevent the seed from being injured by the heat and moisture to which they will have been exposed, from the sun, the rain, and the moisture of the earth. After being sufficiently cured, while dry, let the seed be gently laid on the wagon or sled, and hauled to the barn, using every necessary precaution to ensure, that as little of it as possible be left in the field or scattered along the road.

Mode of cleaning.

Various methods are practised, for cleaning the seed from the chaff. The only two as far as we know, used in this country, are treading it out with horses, or cleaning it in a thrashing machine: The first is tedious, laborious, filthy and unwholesome both to man and beast, the latter is far preferable in every respect, but as all are not provided with thrashing machines and as therefore many must still continue to tread out their seed we will submit a few observations on the mode of performing this operation. Having covered the barn floor with seed in the chaff to the depth of from 12 to 18 inches, put on the horses and tread one day, the next morning run the chaff through a fan, much of it will have been beaten to dust and will be blown away, as will also the light chaff, having no seed, and that from which the seed has been separated, but much the larger portion of the seed, still enveloped in the chaff, will be found in the rear of the fan, this, having been separated from the empty chaff adjoining it, must be again spread on the floor and having added another portion of untrodden chaff, the horses must be again put on and made to tread it another day when it should be again run through the fan as before, the produce of this, will far exceed that of the first day's treading, but still, much good seed will be found immediately in the rear of the fan not yet separated from the chaff—this must be again spread on the floor, and a new addition be made of untrodden chaff, and this process must be repeated until the whole crop is trodden out. The seed, after passing through the fan, should first be run through a sieve, sufficiently coarse to permit the clover seed to pass through, but retaining all larger seeds and trash. It should then be again run through a finer sieve, retaining the clover seed, but permitting the passage through of all smaller substances, by these two processes, the clover seed will be thoroughly cleansed from all kinds of filth and prepared for market. The only advantages derived from cleaning the seed rather than sowing it in the chaff, are the ascertaining with greater certainty the quantity sown and the ensuring a more equal distribution of the seed—where therefore, a sufficient quantity can be afforded to insure the desired thickness in every part of the ground, sowing in the chaff, will not only do as well, but is to be preferred, as it is believed more likely to come up and to stand.

From the Silk Culturist.

SEED TIME FOR THE MULBERRY.

South Coventry, (Conn.) June 25th, 1835.

Sir—The scarcity of mulberry seed the present season having prevented many persons from sowing nurseries in the spring, I take the liberty of informing them through the medium of your paper, that from experiment, I am satisfied that the month of August is a suitable season for sowing the seed. If sown any time during the month of August the seed will vegetate quickly, and by the time of the early autumnal frosts, the plants will have grown to the height of three or four inches. They may then be easily covered with straw and horse manure, which will sufficiently protect them through the winter. In covering them but little straw should be used, otherwise, the rats and mice may be induced to burrow in it, in which case they will most assuredly destroy the plants. If the seed is sown at this season and protected in this manner, they start early the following spring, grow vigorously through the summer, and by autumn attain about the same height as though sown the preceding spring. Another advantage from sowing in August is that seed of the same year's growth may be obtained, which is more sure to vegetate.

J. W. BOYNTON.

SELECTION OF SEED.

* * * The important topic, of the selection of seeds, opens this number, [of the New York Farmer] examples are quoted to show that the successive selection of seed from choice

plants grown in the same situation, is to be preferred to any benefit which changes of seed from distant localities can produce. We in the South practice on the opposite system very extensively; the planters of Bayou Bœuf grow cotton seed from Mexico, and furnish seed to the planters of Petit Gulf; these in their turn supply Louisiana, Mississippi, and Alabama, and from them our Petit Gulf cotton seed comes—gradual changes take place in its character here, and the genuine variety is kept up by annual importations.

It is not to be doubted that instances occur of remarkable improvement both in the quality and quantity of our rice crops upon the use of North Carolina seed rice. And it has been the settled habit of our rice planters from the commencement of that culture on our River Swamps, to draw their supplies of seed from the Inland Swamps; this shows a deep conviction of the advantage derived from change of seed.

On the other hand, Mr. Gibbes, of Chester district, in this state, grows corn known there as the three eared corn, which his neighbors buy for its prolific tendency; this he obtained by selecting stalks having three ears; and every body knows that of late our Sea Island planters have been zealous in the selection of fine samples from their crops for seed; so far was this intent examination carried in one instance, that the long use of magnifying glasses, to aid in selecting the finest fibre, threatened blindness to one gentleman of John's Island, as we are told. he is rewarded by sending to market a "fancy brand."—*South. Agr.*

For the Farmers' Register.

DESULTORY OBSERVATIONS, AND INQUIRIES, ON THE IMPROVEMENT OF LAND.

Charlotte, Va. Aug. 1, 1835.

We are disputing in this section of country whether the three or four-shift system is most suitable to our lands, and I propose making a few remarks relative to this question, as well as some desultory observations on other matters connected with the subject of agriculture.

In order to arrive at any thing like accurate conclusions, it is necessary first to define the terms three and four-shift system, as used in this communication. By the three-shift system, we mean a farm divided into three equal parts, cultivated successively, one year in corn, one in oats, and one in grass. By the four-shift system, we mean a farm divided into four equal parts, cultivated successively one year in corn, one in oats, and two in grass. From this it will appear that on the three-shift plan there is in fact but *one year's rest*—and on the four-shift plan only two—which in my humble opinion, is but a slender chance for *improvement*—that is, where we depend on *grass alone*.

The farm on which I now reside, has been under what is called the four-shift system, for something like fourteen years—eleven of which, I can safely say, there has been little or no grazing during the spring and summer. Occasionally in the months of November and December I have permitted my cows, and sometimes a small head of horses, to glean the fields. My stock of hogs never yet enjoyed the pleasure of the harvest field more than twice or thrice during the fourteen years; and strange to tell, I have never bought pork or bacon, except the two first years of my little farming career. The different shifts have been tolerably well set with herds grass or clover, (wherever either of these grasses would grow) for the greater part, if not the whole time above mentioned. Still my lands are poor and unproductive—and I am now in what is commonly called a *quandary*. Shall I continue my efforts on the four-shift plan—or shall I abandon all hope, and try the three-shift system?

It would, Mr. Editor, be a source of much gratification not only to the writer of this article, but also to many other readers of your valuable Register, to see this subject fully discussed by some of your able and practical correspondents from the tobacco growing country. The excellent remarks already published in your columns, relative to the three and four-shift systems, apply more particularly to the wheat growing country. My opinion, though entitled to but little weight, if any, rather inclines to *change*; and the reasons which influence my mind in relation to this important subject, will be candidly and plainly submitted to you and your readers.

The first which suggests itself in favor of the three-shift, is, a greater proportion of the best land of the farm will annually be brought into cultivation. Now, in order to elucidate this idea as clear as possible, let us take for example, a tract or farm containing 320,000 corn hills, and where tobacco, corn and oats are cultivated, (as is common here) 8,000 per hand of each, is considered fair cropping for an average parcel of hands, although 10, and sometimes 12,000 per hand is cultivated. This 320,000 divided into four-shifts, and worked by ten hands, gives four shifts of 80,000 each. If the same farm be divided into three-shifts, and managed by the same force, we have three shifts, containing about 106,000 hills each. Out of this we may select the best 80,000 for the year's work. The remaining surplus of 26,000 may be sowed down in small grain, which will not materially interfere with, or affect the general management of the crop; or it may be suffered to *improve* by *rest*, and be occasionally cultivated, as time and circumstances may direct. From this view of the question, it would appear a matter easily decided: but then another question arises—does the land improve as much when cultivated once in three years, as when cultivated only once in four? Experience, as already remarked, is but a small inducement with me to hope for much *improvement* to our common lands from *grass alone;* and we may add to this, the combined advantage of non-grazing and deep ploughing. These remarks are intended to apply only to the common corn land of this section of country, or to lands of a midling quality, for there is not the least doubt that fresh land of good quality, or even old land in good heart, under judicious cultivation, with the use of clover, may be not only kept up to its original fertility, but is susceptible of a high degree of improvement. But on the common corn land let me ask what is the improvement of three or four years worth, when, as before remarked, that of ten or a dozen is scarcely perceptible?

Another advantage which the three-shift system possesses, consists in the great saving of labor both in the preparation and cultivation of the crop. It generally requires the greater part of my hands to shrub and clean up the briers, bushes, &c. nearly the whole time of the ploughing season, (say from the 15th November till the 15th of January,) in order to keep the ploughs in motion. This labor would be considerably diminished under the three-shift plan, for the plain and obvious reason, that a bush or shrub is easily cut off, or taken up, at one or two years old, when if permitted to grow, and increase in number, another twelve-months, the labor would be increased nearly two-fold; and we all know the difference between working a field recently cultivated, and one that has not been disturbed for a longer period of time.

Again the three-shift system offers a great inducement to abandon that *pest* on all stiff high land, called *herds grass;* for on the four-shift system with this grass, we only reap the advantage of the grass the last or fourth year, it being hardly discernable the year after seeding; whilst on the three-shift plan we may avail ourselves of the use of clover, which springs up earlier, and affords a much better covering to the land. The clover crop on good high land, and with seasonable weather, may be used moderately the year it is seeded, and yields one of its best crops the succeeding year—which may be called a "nimble shilling," and according to the old adage, is worth at least a "slow dollar."

Lastly by adopting the three-shift plan, the farmer is enabled to turn his attention more to the subject of manure, which to the vegetable kingdom is of the same importance, and sustains the same relation, that bread does to the animal kingdom. And we are here led to ask what is the best application of manure, or what is the best system of manuring? Shall we apply the little that is made to the poor worn-out spots? or shall we give it to those parts of the field which are in better condition? It surely cannot be sound policy to give one bushel of manure to a gulley which will scarcely compensate us for *the time* required to scatter it on—especially whilst we have so much land of a better grade, that will, on a moderate calculation, pay us double.

I have thought, Mr. Editor, for a long time, that many of us who make great pretensions to the subject of *improvement*, commence at the wrong end of the chapter. What would be the difference of product in applying manure to an acre of exhausted land—and applying the same quantity to an acre in good condition? Suppose a certain small quantity of manure applied to an acre which will produce without that aid, one barrel, and the gain should be one-tenth—would an acre capable of producing *two barrels*, gain only one-tenth? But if each acre gains one-tenth, does it not follow as a consequence, that we have taken the wrong end first? Does manure increase the productive capacity of soil in proportion to the quantity applied; or is it in proportion to the fertility of the soil previous to the application of manure? I do not suppose the productive capacity of soil can be the law regulating the increase, unless by that capacity we mean the fertilizing matter already contained in the soil, which possibly may be the case, and is perhaps exemplified in the application of plaster—for we can scarcely believe the very small portion of plaster generally used, could have the effect so frequently seen, unless we reason on this hypothesis. But as a general rule, I am disposed to think the *increase* from manure, is in proportion to the fertilizing matter already contained in the soil, and a particular adaptation of this manure to the soil. Let us take four lots of land Nos. 1, 2, 3 and 4, differing in point of fertility according to their respective numbers; that is, No. 1, producing one barrel—No. 2, producing two barrels, &c. Now, supposing that the same small quantity of manure is applied to each of these lots, which lot will give the greatest return for the application? The gain of No. 1, taking a tenth for the increased production, is one-half bushel—No. 2, gains one bushel—No. 3, gains one and a half—whilst No. 4, gains two bushels, thus showing an increase of product for the same labor and expense, of 300 per cent. This perhaps would be the result until the soil is brought up to its highest point of productiveness, or nearly so, at which time we might take the next number, and so on, until we shall have completed the rotation.

The policy of this course arises from the simple fact, that under present circumstances, we are put up to all that we can do, to make both ends meet, and the plan proposed provides for the *present* a more plentiful return, whilst for the *future* we may remember the proverb—"Sufficient unto the day is the evil thereof."

Opinions on these matters, from any of the readers of the Farmers' Register are respectfully solicited by a subscriber from

CHARLOTTE COUNTY.

ON SAVING CLOVER SEED.

To the Editor of the Farmers' Register.

Granville, N. C. Aug. 1835.

The following extract of a letter was handed me by a friend, a copy of which I send you for insertion in the Farmers' Register. The cause of agriculture is to some extent interested in the dissemination of information upon the subject of this letter. There exists in this section of country a strong prejudice against the use of clover seed sold by the merchant, from the danger of introducing nettles, and other pestiferous plants—and besides, the cost is in a great many instances, an objection to the buying of them. I hope some one of your readers is in possession of a more convenient and speedy means of saving these seed, than the one described below. If so, he would confer a favor on the public by publishing it through the columns of the Register. I should myself be particularly gratified, by seeing a comparative estimate of the trouble and labor of saving the seed, with the cost of purchasing them.

Extract of a letter from Dunkerque in France, in answer to inquiries respecting the culture and manner of saving clover seed in the north of France, and kingdom of Belgium.

DUNKERQUE, *Jan.* 7, 1834.

"The seed is sown from the month of March till about the 20th of May, in ground sown with wheat or oats. It ought to be sown in cloudy, foggy, or rainy weather, as hot sunny weather is apt prematurely to burn part of the seed, and of course make the crop thin on the ground at harvest.

When the wheat or oats are cut, the ground remains covered with the clover plant, which does not require the least care or trouble during the winter, unless being passed over by a wooden or iron roller, where the frost has rendered the ground too light. In the month of May of the following year, they pull out all the thistles, and other destructive weeds, and plants that may be likely to impede its growth, or be troublesome afterwards. In the beginning of July they cut the first crop of hay. This first crop does not give any seed, but the plant grows again, and it is in the second cutting or crop that they find the seed. It is for the farmer to judge when the plant is ripe enough to cut for seed. However, it appears necessary it should be quite ripe, or apparently dead. They then dry it well and stack it, and when dried or deadened, they thrash it out with flails, in the same way they formerly used to take out grain in Scotland. It is, however, very difficult to part the seeds from the husks of the clover plants, and then it requires all the skill and ingenuity of the farmers, with their fanners, rakes, sieves, &c. to cleanse it so as to please the English, and more especially the Scotch farmers. This plant is generally sown in land which requires rest, and is followed by a crop of wheat. Thus they will in the year 1833 have wheat in which they sow clover seed in 1834. They gather the harvest of clover seed in 1835—they have wheat again, and in 1836, a crop of flax. This mode of culture generally produces the finest quality of flax, but the land must be good and rich.

"If any further information regarding this or any other of our productions, can be useful to you, or your American friends, you know you have only to say so, and to command my services."

T.

The above you will publish or not, at your discretion, in the Farmers' Register. The subject attracted my notice from its being the first account I have seen of a method of saving clover seed. I hope (more for the benefit of my neighbors and others, than of myself, for I never expect to gather the seed, although I sow it to some extent, and intend to do so quite extensively hereafter,) it will turn out that the ingenuity of some of our Yankee brothers has already invented a machine or a mill, for the purpose. If they have not it seems to me from the nature of the thing, a matter of surprise. The introduction of clover into the county of Granville, is of recent date, and until the last two or three years, its successful cultivation was regarded as an experiment. This experiment has, however, been fairly made, and its success has fully realized the most sanguine expectations, so that the crop is now coming into common, and in some instances, into extensive use; and I doubt not will, with the herds grass and other artificial grasses, in the course of a very few years, greatly improve our system of agriculture. The doubts heretofore entertained with respect to the culture of clover, were formed with reference to the heat of our summer months, and not to the character of our soil, which is generally well adapted to the growth of tobacco and wheat, and of course, in the absence of other opposing influences, to clover.

[There are several objections to mowing clover to save the seed, for the farmer's own use. The stalks and leaves, which, if left, would help to enrich the land where they stood, are taken off, and with much labor, to be carried out again for the same purpose, even if not wasted. A large proportion of the seeds are harvested green, or, if waited for, to ripen, the early ripe will have been mostly wasted. Bad weather, after mowing, will cause much more loss of seed, either by shattering or sprouting. The seeds then must be separated from the stalks by treading or trashing, and fanning, at considerable cost of labor. Finally, all the seeds of bad weeds, ripe about the same time, are saved with the clover seed, and carefully sown over the other best parts of the farm.

There are contrivances to pull off the ripe heads of the clover, by means of an edge formed into long teeth like those of a comb. The smaller kinds are worked by hand—the larger drawn on wheels by a horse. This plan seems to be free from most of the objections stated above, and to promise well in theory. Nevertheless, in 40 years it has not worked its way any where into general use, and very few farmers in Virginia have used, or continue to use this plan.

There is another mode which would seem the most slow and tedious of all—but which we think decidedly preferable both to buying the seed, and to saving them by mowing and thrashing. This is to pull off the heads by hand. When there is plenty of crop to gather, and there is no objection to leaving a large proportion—and even though the growth is irregular or in spots—women, stout boys, and girls, will gather from eight to ten bushels each a day. These are of course only the heads containing ripe and perfect seed—and no seeds of bad weeds are mixed with them. The seed live and thrive better by being sown in the chaff—and the only objection is the great difficulty of regulating the quantity. If equally distributed, six bushels in the chaff are enough for an acre. In this manner every day's work is saved, by putting the seed in a house as fast as gathered. No bad weather causes loss, except by interrupting and preventing the gathering. Where there is the proper kind of labor to spare in August (which however never can be where there is cotton to pick out,) it is seldom so profitably employed as in this seemingly slow way of saving clover seed.]

THE IMPROVED POCKET CHONDROMETER.—SKINLESS OAT.

To the Editor of the Farmers' Register.

This being a very useful little implement, and probably not generally known to your subscribers, I take the liberty to send you a description of it, together with a copy of the printed table pasted on the inside of the small box containing the implement itself. Its use is to ascertain the weight per Winchester bushel, of all kinds of grain or seed, which it does very accurately. The principle on which it is constructed is that of the steelyard. It consists of a very neat little brass standard, six inches high, with a circular bottom about two inches diameter, a small bar about nine inches long, part brass and part steel—the brass part graduated, and having a small brass weight made to slide on it so as to mark by its edge the number of pounds per bushel, of the grain or seed intended to be weighed. For the other end of the bar there is a little brass bucket made to contain about a gill, struck measure, which is to be carefully filled with whatever you design to weigh, when the bar is fixed on the standard, and the brass weight being moved until it balances the filled bucket, ascertains precisely, the weight by the struck Winchester bushel.

Copy of the accompanying Table.

Seventeen specimens of marketable grain and seed.

Wheat is from	55 to	63 lbs. per bushel; mean wt.	59
Rye,	50	56	53
Barley,	45	49	47
Red clover,	60	64	62
White do.	66	70	68
Dutch clover,	65	71	68
Hemp,	38	42	40
Linseed,	44	50	47
Turnip,	48	50	49
Oats,	35	42	38½
Meadow grass,	10	18	14
Rye do.	12	20	16
Cinque foil,	22	28	25
Peas,	62	67	64½
Small beans,	60	66	63
Canary,	54	56	55
Rape,	47	50	48½

The use of this little implement will be obvious, I think, at first sight; for it furnishes, at once, a more convenient and expeditious mode than any I have known tried, of ascertaining the comparative weight of all our varieties of wheat, corn, rye, and oats; and as their value generally, is in proportion to their weight, it is a matter of some importance, as well as curiosity, for every farmer to possess so easy a means of ascertaining which is the heaviest. I have very often used this instrument, and in several instances, have sold my wheat by it—the purchaser being perfectly satisfied with this mode of determining the weight. By this I find the weight of the skinless oat to be 47 lbs., whereas the heaviest oats in England, (as you will see by the table,) weighs only 42 lbs. As you may never have seen this new variety, which has lately been introduced into England from China, and cultivated with great success, I send you a few grains as a sample. Last spring I purchased from one of William Prince's agents, in our neighborhood, a single quart, at the rate of $16 a bushel! One pint of these I drilled in my garden, nine inches apart, the wide way, and two inches the other, as near as I could prevail on the hands employed to drop the grains at that distance; but they were probably nearer. In this way the pint sowed 247 square yards, and produced 116 pints of such grain as I send you. The produce would have been something more; for three spots, each about six or seven feet square, were lodged, and consequently injured. The average height, when ripe, was about four feet, and the appearance then, by far the most beautiful of any small grain I ever saw. From the looks of the grain I should judge it would make very good flour; but for horse feed it must certainly be vastly superior to any other oat yet discovered. To judge by my single trial, they will make at least as much, by measure, as any of the kinds we cultivate, and will so far exceed them in weight as to give them a very decided preference. Be all this, however, as it may, I have determined to sow as many bushels of them next spring, as I can procure: not however, at sixteen dollars a bushel.

JAMES M. GARNETT.

MOVEMENTS OF THE ABOLITION SOCIETIES; AND ANTICIPATED RESULTS.

For some years past, the small, but growing and active sect of abolitionists in the Northern States, have been bringing their theories respecting slavery into practical operation: and the effects have recently assumed an importance which threatens seriously to affect both the agricultural interests and political rights of the Southern States. This sect, composed of bigoted and reckless zealots, who avow their aim to effect, if possible, the entire and immediate abolition of slavery, at all hazards, and without regard to consequences—has increased rapidly in numbers and strength. Nor is this strange. The detestation of slavery, in the abstract, is a feeling almost inseparable from man's best feelings; and thousands of slave holders—who will, if necessary, defend their rights against the attacks of the abolitionists, at the bayonet's point—would make far greater personal sacrifices, in any feasible and proper manner, to mitigate the evils, or remove, if possible, the existence of slavery, than those who condemn and denounce them. It is the easiest thing in the world to be charitable at the expense of other people—and there never will be a lack of fierce advocates for the removal of this evil, though by producing evils ten times greater, so long as all the losses and dangers from the change, whatever they may be, must fall on those far removed from the zealous and ferocious "philanthropists"—who are striving to put fire to a train of gunpowder, because they are in perfect safety from the awful and destructive explosion that may follow.

These societies, lately deemed so contemptible, and now perhaps as incorrectly elevated to a most imposing station of power and influence, are now using systematic efforts to reach their end. More than 200 affiliated abolition societies in the Northern States, have already been organized, to labor for the good or the ill of the South: large amounts of money have been collected—secret emissaries are employed in the South—from their presses numerous publications are issued, filled with misrepresentations and falsehoods, addressed to the supposed feelings of the slaves, and to the degraded understandings and besotted prejudices of the lower class of their northern countrymen—and these publications, through the mails, are sent free of carriage (to the publishers) to every part of the south, as well as of the north. These violent and open proceedings, and the strong suspicion that even worse are in secret operation, have roused the south, and drawn forth a burst of indignation, and expression of determined resistance, which will be universal. In this matter, at least, there are no party divisions to distract our views, and to prevent a united effort to maintain our interests and rights. Whatever may be the issue, the people of the south will, in defence of their rights and property, act as one man. Public meetings are every where called. They have been already held in Richmond and Petersburg, and with a unanimity without precedent, resolutions have been passed expressive of their feelings of indignation and of approval of such legal and proper measures, (and perhaps rather exceeding the legal limit,) as may be deemed necessary to guard against these assassin-like attempts. The circumstances of the very recent discovery of an intended insurrection of slaves in Mississippi, instigated, planned, and intended to be led (as is alleged) by white men, some of whom were emissaries of the northern abolitionists, have served to add fuel to the flame, and to increase the bitterness of denunciation, and of hostile feeling.

So far as the opinions of the South, (as proceeding from public meetings, and from the press generally,) are expressive of indignation at the movements of the abolitionists, and of determination to resist, *at all hazards, and to any length*, the practical execution of their theories, (even in the slightest particulars,) they command our entire and hearty approbation. But we greatly doubt the propriety and the policy of attaching much importance to the ravings of the abolitionists, and to their circulation through the press and the mails. The violence of effort openly exhibited in endeavoring to suppress these publications (even if entirely successful in the attempt,) may have as ill effects on those for whom these publications were designed, as their circulation: and perhaps worse may be there by increasing the apparent importance of the writers, and possibly their influence and power, far more than their own labors could as yet have effected.

We do not intend to discuss the question of right, or policy of the institution of slavery as it exists in these states. We should disdain maintaining the argument to defend our rights, or to urge our claim of property. Whatever may be the evils of our system of slavery, (and we deny not that they are many for the slave—and still more for their masters,) the matter is *our own concern*—and we will not consent to its regulation being touched by the people of the north. And while they will confine their efforts to mere *words*, they will meet with no success in exciting the slaves (of Virginia at least) as a body, to insurrection. There would be at least as much prospect of success, if the attempt was made, by writing and printing on this side of the Atlantic, to stimulate the peasantry of Ireland, or even the better informed poor population of England, to cut the throats, and seize the property of the rich. But though the object of the abolitionists is altogether visionary and impracticable—and would be an object for derision and contempt, but for its probable accompaniment of horrors—still they *can*, and probably *will*, (if at all *countenanced by the better judging majority of their countrymen*,) produce effects of awful importance, and affecting deeply and permanently, the welfare of the people of the United States, and the permanency of their present general government. The utmost direct effect of the efforts of the northern provokers of insurrection, would be conspiracies of slaves, detected before maturity, as recently in Mississippi, and visited awfully, illegally, and without just discrimination, on the heads of black and white—of the innocent as well as the guilty—or partial massacres by the blacks, as in Virginia in 1831, which however atrocious, and afflicting to individuals, would be nothing as a war measure, and would draw down most certain vengeance and destruction on the heads of the murderers. Whether such effects may be great or small, the sure and inevitable result must be, that whatever evils may be brought on the whites, will cause ten times as much to the race which the "philanthropists" are aiming or professing to serve. If any one desired the greatest possible amount of misery to be inflicted on the slaves of the south, by any means, and without regard to other consequences, he ought to wish for the increase of the numbers, strength, and power of the abolitionists of the north.

The Southampton massacre is often brought forward as proof of the impending danger of insurrection. To our understanding of those deplorable events, and the consequences, (and we had good means of knowing them,) they prove directly the contrary. The insurrection of Southampton was gotten up and sustained through the brief course of thirty-six hours, by the concurrence of several circumstances, some of which are so rare that they never can be again looked for. The leader was a man of uncommon power of mind, yet touched with something of insanity—a religious enthusiast, who had persuaded himself, and some of his ignorant followers, that he possessed prophetic, and perhaps other supernatural gifts. While this delusion (and the disease,) served to gain him his first few followers, he had cunning enough not to impart his design, even generally, but to two, until the day of the outbreak, and to but six or seven in all, before commencing the first and most murders on the sleeping and unsuspecting victims. If the secret had been committed to even fifty, and for a single week, there is no doubt but it would have been divulged, as in every other case of conspiracy. A powerful aid, also, to the most successful of insurrectionary movements in this country, was that it was the season for distilling; on every farm new brandy was found in abundance, and its maddening power was kept in full operation to gain recruits, and to stimulate them to acts of butchery. Their whole bloody progress manifested the deeds of men made frantic by the conflict of drunken valor and the cowardice of their nature, or of education. The band never reached fifty in number, and half the recruits were forced by threats into their ranks, and most of the others were deluded by false statements of their force and success, which were almost equal in power to actual constraint. They murdered fifty five persons, all surprised and defenceless, and mostly women and children, before their movements were enough known to cause resistance—and as soon as the least effective resistance by armed whites was made, the whole band broke and fled, scattered in dismay, and not the slightest attempt was made to rally, or repeat the effort. All the guilty perished—and unfortunately more than the guilty, from the madness of the times, such as will always be excited by such events—and of which awful fruits will always be produced, when an infuriated people (as lately in Mississippi,) take the execution of law and justice into their *own* hands—which is equivalent to having both law and justice completely put aside, and their place taken by the ignorance, delusion, and worst passions of men.

The efforts of the mad abolitionists of the north, (or of their more temperate countrymen, who claim to be friends of southern interests, because they are for at tacking slavery slowly and gradually,) may cause repetitions of such events, and their equally deplorable consequences: but they will only serve to destroy whatever amount of happiness and contentment is now enjoyed by our slaves, and produce to them misery, if not destruction, without there being a semblance of hope for effecting, by any of their efforts, the object of a peaceable extinction of slavery, and elevation of the condition of the blacks to equality of right and power with the whites.

It would be useless to remonstrate with the abolition societies and their leaders—to address ourselves to the reason of men who insanely expect to reach their objects through the desperate means which they use—or to appeal to the sense of rectitude of any, who, even for a desirable end, would willingly resort to means so abominable—so murderous in their tendency. But we would address our language of complaint and of warning, to the great majority of the citizens of the northern states—who declare themselves friends to the south, and utterly opposed to the schemes of the abolitionists—in the hope of inducing them to exert their counteracting influence, and to put down the nuisance—to use the power which the great body of any community on the right side must always have over a very small portion, considered by that majority as altogether in the wrong. We would ask of the reflecting, to say whether the movements of the abolition societies are likely to effect their avowed object, even if the object is thought desirable—and of the prudent and calculating, to consider whether any results disastrous to the interests of the south, would not also necessarily and greatly injure the interests of the north.

We are assured, from the north, as with one voice, that the abolitionists are but a few, scorned and contemned by the people generally, and by all of worth and high character. Still this despised handful of men, call and hold public meetings to disseminate their doctrines, in every town—have openly established, and keep in operation, presses to flood the south with incendiary publications—and instead of being put down by the force of what is said to be the public and general opinion, are permitted to proceed in their course without impediment of any kind. The reply is ready, that these acts, however detestable, are not in violation of existing laws, and therefore cannot be restrained. It is not for us to point out the remedy—but we beg leave to submit a similar case for illustration.

The people of the southern states are very generally opposed to the policy of forcing manufacturing, or other pursuits of industry, by protecting duties—by the operation of which, it is considered, that they and their country are heavily, unjustly, and illegally burdened, to furnish millions in indirect bounties, to northern capitalists. Very many of us in the south, upon general principles, as well as in regard to our general interests, are as hostile to this policy, as any calm and dispassionate abolitionists can be to the existence of negro slavery. Now suppose that a few thousand of our zealots—(for they are to be found in all parties and sects—) were to carry to such excess their hatred of this iniquitous policy of our government, as openly to league for its destruction, by inflicting loss and destruction on the interests and persons supported and enriched by protecting duties—that they provided materials and employed agents to burn the factories of the north, and to poison the proprietors and superintendents: that under a philanthropic horror of the enormous mass of suffering which is certain soon to reach, and then forever to attend the laboring manufacturers, (far worse than the sufferings of our negro slaves—) that all means of seduction were addressed to this class, including the plunder of their employers' property, to urge their joining in and becoming the most efficient agents of the work of destruction. Suppose that the preparation of means for these ends was carried on without disguise—that proselytes to the hellish design were continually and zealously sought by public meetings, and publications, in many southern towns—that the leaders and principal actors were all known, and even proud of their notoriety—and that nothing was hidden except the operations of their emissaries, attempted or executed in the northern states. Suppose farther, that with all this unlimited malignity of intention, the actual effects produced were comparatively trivial, and that the northern manufacturers, in fact, feared their enemies as little as slave holders have to dread the now avowed abolitionists: still—would such a state of things, and its evident increase, be patiently borne by the north, and the southern states be held as friendly? Would the plea be valid that "these villainous plotters were but a few, held in detestation and contempt by the great body of southern people, who would rejoice no less than their northern brethren, to see such miscreants meet with merited punishment, if the laws were such as to permit any to be inflicted: but that no existing laws had been violated by the known acts of these men in the south—and when they carried their proceedings to the northern states, it would be for the latter to apply the proper punishments—in the propriety of which, (and in aid of which, if necessary,) the south would heartily concur." If such declarations would serve to justify us in the opinions of our northern brethren, we ought to receive as equally entitled to respect the reasons given for the impunity and unmolested progress of the bold and open conspirators and incendiaries of the abolition school.

From the Arcana of Science.

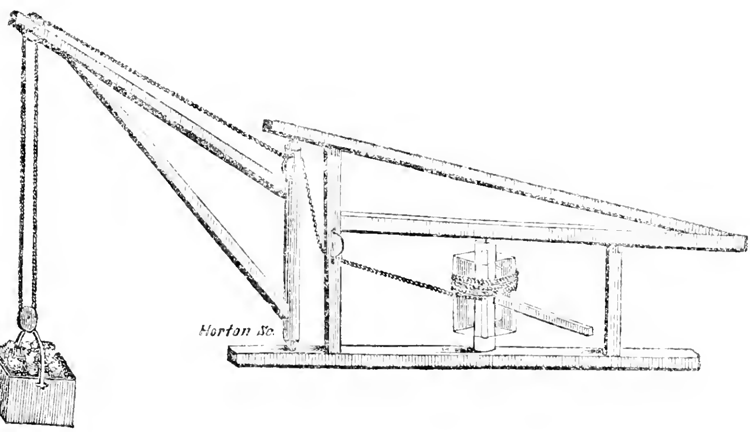
HOUSE FLIES.

On April 7, the Secretary of the Entomological Society read a paper by Mr. Spence, detailing a a curious mode, adopted in Italy, of excluding the house fly from houses. The plan consisted simply in straining a net, made of white thread, across the aperture of an open window: the meshes of the net were about half an inch in diameter. It had occured to Mr. Spence, whether it could be the dread of a spider's net which caused the flies to avoid the thread net, but on consideration he had determined otherwise; and he was totally at a loss how to account for so singular a circumstance.

For the Farmers' Register.

MACHINE FOR RAISING MARL.

In your Essay on Calcareous Manures, you give instructions for digging and carting marl. This method I pursued for several years, but found the labor hard on my hands, and tedious. Marl here is generally found in deep ravines, or in wet grounds. My operations have been slow, from the difficulty of making firm and lasting ways, and the labor of ascending steep hills. Last winter I made a model, and this spring I built a machine for raising marl, to be worked by a horse. I have been using it to advantage, and now send you a draught of it, as it may be useful to those who have wet marl pits like mine. By means of a pump to throw off the water, pits may be worked at a considerable depth; and even if marl is dry, if it lies deep, I think it may be used to advantage. I use two boxes, and by means of hinges and a latch, the marl is discharged from the bottom. I have double blocks: the rope passes through the swoop about eighteen inches from the end, and runs down to the post which supports the swoop, and passes through it, on a small roller, and in like manner through the next post, to the cylinder, to which a reel is attached to increase the motion. The post which holds the swoop and the cylinder, runs on iron pins let into thimbles. The lever is in two pieces, one fastened in the cylinder with a groove at the end, into which the other is let, and secured by a sliding iron clamp. When the marl is discharged from the box, and the swoop swung round over the pit, in nautical phrase, by unshipping the end of the lever, the rope unwinds, and the box descends without moving the horse. The circle in which the horse travels ought to be twenty-one feet in diameter, and the second and third posts supported by side braces.



The cost of the machine is small, though I cannot make an exact estimate. The carpenter who did the work, was hired by the day on the farm, and was taken off with other jobs: but his bill could not exceed eight dollars. The cost of the iron work was ten, and one hundred and sixty-five feet of inch rope, at eighteen and a half cents a pound. The timber, taken from my own woods, may be estimated at five dollars. The rope I find soon wears out, and I intend to supply its place with a light iron chain.

When the marl is uncovered, with one efficient hand in the pit, and a less efficient one to discharge the boxes and drive the horse, five hundred bushels may be raised in a day. The work is not oppressive to the laborers. The teams stand on high, dry ground: no sloughs to plunge through, and no hills to climb. The swoop is turned by a small rope over the carts, and the marl immediately discharged into them. I work four carts, with two sets of oxen to each. They came out of the winter lean and weak; and now with green clover for their food, at the distance of a half to three-quarters of a mile, I draw out from four to five hundred bushels a day; and my oxen have improved. My work goes on with ease and expedition, without stoppage to mend roads, or to clear ditches.

WILLIAM CARMICHAEL.

Wye, Queen Anne's co. Md. July 15, 1835.

CULTIVATION OF BEET-ROOT SUGAR IN FRANCE.

A hectare of land (nearly $2\frac{1}{2}$ acres) sown with beet, produces, in most cases, 2,400 kilogrammes of the root, which is equivalent to 47 cwt. 36 lbs. avoirdupois; and there are many instances in which a single grower raises from 80,000 to 90,000 kilogrammes (6,260 to 7,098 cwt.) The cultivation costs the farmer about 8s. the 1,000 kilogrammes (20 cwt.) The quantity of sugar extracted by the present process is in the proportion of seven or eight parts of saccharine matter out of 100 parts of the raw root. From the molasses, sugar is obtained, and the pulp furnishes nearly as much fattening food for cattle as the root in its simple state; the leaves also are much sought after by the grazier for his cows during those months of the year when green fodder is not easily obtained.—*Printing Machine, No.* 24.

From the Silk Culturist.

CLIMATE AND SOIL OF NEW ENGLAND.

Almost every newspaper in the country has an occasional paragraph on the culture of silk, and in many of them we notice the climate and soil of New England, spoken of as admirably adapted to rearing the silk worm and the cultivation of the mulberry. Remarks of this kind have a tendency, not only to make an erroneous impression but to mislead other sections of the country into a belief that there is something peculiar in our climate and soil, which gives us advantages and facilities, in this respect, not enjoyed by others, while, at the same time, precisely the reverse is true. That providence in the distribution of its gifts has given us a climate and soil congenial to the production of silk is a matter of fact, and ought to be of gratitude and thanksgiving; but that it has lavished them upon us in greater, or even equal profusion with some of our sister states is not true.

The middle, southern, and western states, have natural advantages for the culture of silk, which the northern can never enjoy. The white mulberry will grow luxuriantly in all parts of the United States, and so far as its foliage is depended upon for the subsistence of the worm, the natural advantages of all the states are equal. But with respect to the Chinese mulberry, it cannot be cultivated in the northern states, without much additional labor and expense; while at the south no extra care or precaution is indispensable to its propagation. This gives the southern section a decided advantage over the northern, which no amount of skill or experience, can counterbalance. The whole truth about it is, a portion of the population of New England, and especially of Connecticut, have been for about half a century engaged in the culture of silk, and their experience and observations have constituted a fund of practical information on the subject, which cannot be found in any other part of the country. The success of the silk business in Connecticut, is therefore attributable to this cause, and not to any peculiar adaptation of climate and soil, for in this respect we are far less favored than most of the other states.

From the New York Times.

CULTIVATION OF SILK.

It is little more than fifty years ago, since an American vessel was seized at Liverpool for having on board eight bales of cotton, it not being believed that the article could be produced in this country. At present about 600,000 bales are carried to the same port. To the culture of this article the country owes a great part of its wealth and prosperity. Where fifty years ago eight bales of cotton were produced, one million two hundred thousand are now produced. If fifty years ago a man had ventured to predict that the article of cotton would become the grand staple of the country, and add millions upon millions to its wealth, he would have been laughed at as a madman. It has lately been predicted that before many years are passed, the production of silk in this country will equal the production of cotton; and we see no reason to question the justice of the calculation. The cultivation of this article has been commenced by the enterprising men of the east. The soil and climate of New England are admirably adapted to its cultivation. Those who have thus far engaged in it, have reaped good profits, and have every reason to persevere. It has commenced in a part of the country where thrift and industry have never failed to succeed. It has been commenced under far more favorable circumstances than those which attended the first cultivation of cotton. It requires but little labor, and the principal part of the labor required may be performed by females and children. The experiment has thus far proved successful, and it has been attended with but a trifling degree of expense.

A MODE OF DESTROYING ANTS.

A writer by the name of Roughly, says: "Poisoning with arsenic is the most expedient mode of getting rid of ants, as the living will feed on the dead, so that the whole nest, (by devouring one another) are thus killed."

From the Northampton Courier.

PLOUGHING UNDER GREEN CROPS FOR MANURE.

Being the owner of a small farm, most of which was in a low state of cultivation at the time I commenced making experiments, and feeling desirous of enriching it faster than I could with stable and barn yard manure, the quantity made being small I therefore resolved to try the effect of ploughing under green crops. The piece upon which I tried my experiment contains nearly four acres, and is of a hazle-nut colored loam, lying near the Connecticut river.

In 1831, the lot above mentioned had wheat and rye reaped from it; about $1\frac{3}{4}$ were of wheat, and produced 17 bushels, yielding $9\frac{5}{7}$ bushels to the acre. The $2\frac{1}{4}$ acres of rye yielded about 27 bushels being 12 bushels to the acre—total of wheat and rye, 44 bushels. The ground for the wheat was ploughed three times and had the same number of harrowings. That for rye was ploughed but twice, with two harrowings; clover and herdsgrass were sown on the whole piece. At the time of raising the grain, I did not intend trying any experiment; but the grass seed not having come up well, the lot was ploughed once in August, 1832, and sown with rye, was fed down with sheep in the fall and also in the spring, until about May; thus affording sufficient feed to pay the expense of the seed for the first crop.

After the sheep were taken from the grain, it was left to grow until about the time it blossomed, when it was ploughed under, and the ground sown with buckwheat—$\frac{1}{2}$ bushel of seed to the acre. When the buckwheat was in blossom, that was also ploughed under; after which the ground was suffered to remain until a short time before it was sown, when it was again ploughed once, sown with wheat and rye, October 3d. Previous to sowing the wheat, the seed was soaked about twenty-four hours in brine, and afterwards rolled in plaster, where it remained in a body twelve or sixteen hours. My object in treating it in this manner was to prevent smut, and the ravages of the Hessian fly, which has several times destroyed some of my wheat; but fortunately the crops the present year were uninjured by them. The rye was sown in its natural state.

In the spring of 1834 the whole piece was plastered with about two bushels to the acre. It was sown for the purpose of benefiting the young grass, and it has now (spring of 1835) come up well, and bids fair to produce nearly twice the quantity of feed usually obtained from it in a season. The quantity of grain which the piece produced the past season is as follows: About one acre was sown with white flint wheat and yielded 16 bushels—2¾ acres were sowed with red bearded wheat, and produced 33 bushels, making in all 49 bushels or 14½ to the acre—⅝ of an acre was sown with rye and yielded about twelve bushels, being at the rate of 19½ bushels to the acre. The increase of the wheat crop, according to the above estimate, was more than 49 per cent. and that of the rye more than 59 per cent. Had the past season been favorable for wheat crops, I doubt not that I should have obtained eight or ten bushels more. Perhaps some may think the plaster caused the last crop to be better than the preceding one; but I do not think it was, as I sowed some on a piece of rye the past season, a part of which was left unplastered, and it could not be discovered that the plaster benefited either rye or land—the soil was the same as that on which the wheat was sown.

From the [British] Quarterly Journal of Agriculture.

IMPORTATION OF THE BONES OF CETACEOUS ANIMALS FROM THE POLAR SEAS FOR THE PURPOSES OF MANURE.

The great consumption of bones occasioned by the increasing demand for bone-manure in the extension of turnip husbandry to the more remote and inaccessible parts of the country, accompanied with the small indeed, but gradual, rise in the price of that valuable means of fertilizing the soil situate at a distance from large towns, naturally creates the apprehension that at no distant period the demand will outrun the supply. In order to anticipate such an "untoward event," our thoughts have lately been turned to a prolific source of supply which has hitherto been almost entirely overlooked—we mean the Polar Seas. Much valuable bone might be brought home in the whale ships from those regions. One large whale might afford several tons of bones. We are quite aware that while the prospect of an abundant supply of blubber arrests the attention of the whale-fisher, he will be regardless of the bones of the animal. This state of the mind is natural. The fisherman, when so actuated, only fulfils the principal object of his voyage, and were he always certain of loading his ship with the most valuable part of the cetaceous animals which he captures, no one should be so unreasonable as to request him to direct his attention in the short time he has to accomplish his object to any other subject. But we all know how very seldom whalers bring home bumper ships, how much more frequently the ships are only half loaded; while every year some come home clean. Now some of their time might be profitably, at least usefully, employed in securing a quantity of the bones, such as the jaws, ribs, and vertebræ of the animals which they capture, and although it would not be desirable to occupy the most convenient parts of the ship with bones, while there was a prospect of obtaining blubber, it should be remembered that no bones can be obtained without in the first place securing the blubber. It will, no doubt, not unfrequently happen that the most successful periods of the fishing, are those when the capture of whales takes place faster than the blubber can be removed from the carcass and stored by; and we have heard a whaler assert that they have had fourteen carcasses floating alongside awaiting the process of fleecing. But if the whole bodies can be kept floating alongside to await the convenience of the crew to remove the blubber, cannot the fleeced bodies in like manner be kept floating till it is convenient to disengage some of the bones? Bones are easily disengaged, and would be of easy stowage. They could be cut into junks with cross-cut staws made for the purpose, and many of them used as wedges to secure the butts in the hold, while others could be stowed away in any space in which a butt cannot be stowed. In this manner any ship could bring home many tons of bones; and it might be an understanding among the masters of the ships on the fishing ground, that if one ship was much taken up with the storing of blubber, while another was less successful, the latter might get leave to tow away the fleeced carcasses to their own ship. We have heard it stated that the bringing home of bones would be a question of freight with the owners of the ships. We think this is a mistake, for the mode in which whale-fishers are paid has no reference to freight. They are paid according to the tons of blubber which they bring home. Some bones have been brought home of late years; one ship from Leith last season we saw brought four or five tons; but what is that trifling quantity compared to what she might have brought when she came home little more than half laden? The mode adopted by the owners for paying for bones, is to give the crew one-fourth of their value, so that the question of freight has nothing to do with the matter. We wish the owners of the whale ships from Scotland would seriously take this matter into consideration, and encourage their crews to stow as much bone as they conveniently can at their leisure. The value realized by the bone might not only pay the expenses of delivering the ship, but might even reimburse the owners for the loss of the bounty, over and above the value of the blubber in an average voyage. If a premium of a piece of plate from the Highland Society would be any stimulus to the captains who would bring home the greatest quantity of bones, and thus forward our views for the benefit of agriculture by a constant supply of a cheap and efficient manure, we are sure they will be happy to grant such a prize to the successful competitor, and the owners we are assured would be proud that it was one of their ships which had carried off the honored prize.

From the British Farmer's Magazine.

REMARKS ON THE SCARLET TREFOIL.

Addressed to the Conductor of the Gardener's Magazine, and communicated by MR. LOUDON.

As the scarlet trefoil (*trifolium incarnatum*) has already engaged the attention of agriculturists, and from its valuable properties is likely to be brought into general use, permit me through the medium of your periodical, to offer a few observations on the best mode of cultivating it.

It is well known, that all the clovers like a solid bottom; and from experience it appears that such is more particularly the case with the scarlet trefoil. When the land upon which it has been sown has been rendered fine and light, by repeated ploughings, the crop has frequently been an entire failure. Such failures have been attributed to the depredations of grubs; but there is much reason to believe that, the plant perished in the winter, owing to the lightness of the soil, as I have never heard of a single instance of failure when the seed was committed to an unploughed surface. In the beginning of October, 1833, I sowed a plot of garden ground, the soil being strong and rich, upon a chalk bottom. The seedlings came up well: but, in the course of the winter, all perished, with the exception of a single plant. In September, of the same year; Colonel Beach sowed a few acres in a field, about a hundred yards distant, which he had ploughed and dressed for the purpose, the soil in this case being of a similar nature to that mentioned above, and here again the crop was a failure. At a distance of about two hundred yards, and upon soil precisely similar, and in the same season, a stiff, unploughed wheat stubble produced as fine a crop as could be desired. The farmer, who had this crop, had previously pursued the same plan, and had realized from his produce upwards of £40 per acre! I find, also, that the crops have frequently failed in the county of Essex, where the ground had been ploughed before sowing. In September last, I sowed four and a half acres upon a barley stubble, without any preparation whatever, and there is an abundant plant. I do not mean to assert positively that, no crop will follow after ploughing: but experience proves that success is very doubtful when this is done.

With respect to the properties of the trefoil, I do not believe that there is a more hearty green food in existence. Cattle are extremely fond of it. Farm horses, during their spring work, may be kept in the highest condition upon it, and after affording abundant feed, may be cleared off in time for turnips or barley, both of which, upon trial, have succeeded perfectly well after trefoil.

Should these observations prevent disappointment, or be the means of drawing the attention of the farming interests to the facts of the case, it will be satisfactory to their friend,

MATTHEW HARRISON.

Church Oakley,
Near Basingstoke, November, 1834.

P. S.—Scarifying the ground has been found to answer well; and where the surface is foul, it is certainly advantageous.

From the Claremont, N. H. Eagle.

SHEEP.

It is a well known fact, that wool growers in this section of the country, whose flocks exceed 200 sheep, lose a large number of their sheep each winter. Some of them, we will allow, die of old age; but too many of them do not live more than two years. There is a remedy for this loss of property and that too directly in the hands of the shepherd. This being the case I am anxious to lay it before the public that all may profit by it hereafter.

It is a custom among many farmers, when they drive in their flocks in the fall, to put the whole flock together in a single barn, shed, or whatever place they may happen to have to keep them in. Now it is very evident that the young, the very old, and weakly, or in other words, the most unhealthy of the flock, cannot possibly fare equally well with the rugged, and it is a fact while the one is thriving the other is losing its strength. When kept in this situation, one after another falls from hunger, and other causes incident to this state of affairs, and they are no longer able to raise themselves. Here the shepherd for the first time separates the almost lifeless sheep from the multitude, and endeavors to restore it to health. But it is too late. He is soon convinced that "a stitch in time saves nine"—that ten thousand dying sheep, are worth no more than the wool on their backs.

When sheep are brought in from the pastures, in the fall, they should be divided into four distinct flocks, viz.

1st. Meagre or sickly—which should be kept in a warm barn, with but few in a pen. They should have salt as often as once a week—should have a handful of corn each day through the winter—as much hay as they can eat through the day, and should be watered as often as twice a day. This will not fail to keep them in good order.

2d. The ewes also should be kept from the rest of the flock and should receive the same treatment with the exception of the green which may be given occasionally, though it is not necessary.

3d. The bucks, intended for the benefit of the flocks, should be kept by themselves, that they may be in good order, and for another reason that will suggest itself to all wool growers.

4th. And last of all are the wethers which may be, if healthy, kept entirely on hay and water.

I have for twelve years kept a large flock of sheep, and have lost a great many; but since 1830 I have adopted this course and have not lost one-tenth as many as I did in the same number of years preceding that time.

AN OLD FARMER.

From the Annales des Arts et Manufactures.

DURABLE WHITEWASH.

I am enabled to certify the efficacy of marine salt in fixing whitewash made of lime. In the year 1795, when I was director of the naval artillery at the port of Toulon, I was commissioned to ascertain the utility of a method proposed by the master painter of that port, M. Maquilan, for whitewashing the ships between deck, and likewise their holds, in a durable manner, by means of lime. Our report was in favor of this process, which consists in saturating water in which the lime is slacked with muriate of soda, (common salt.) The whitewash produced by it is very permanent, does not crack, nor come off upon one's hands or clothes. The experiment was made only on wood. It appears from M. St. Bernarde's account, that it succeeded equally well on walls.

THE PITCHER PLANT.

Few plants if we consider the structure of its foliage, are more interesting than the pitcher plant, of Southern India. It is found in Ceylon, Java, and other islands in the Indian Archipelago. It has been transplanted into several gardens in England, where it attains to great perfection. Its stem is eighteen or twenty feet. It branches out over the wires prepared to support it; and bears numerous leaves, in the form of a pitcher, and which look more like art than the production of nature. The leaf, including the stalk, is two feet long. The pitcher is rather an appendage to the leaf, than the leaf itself. It is hollowed out like an elongated pitcher; and is eight or nine inches long. It is attenuated at its base, where it is curved or arched, and then suddenly turns upwards. In its young state, it is covered by a lid or operculum. After a time, the lip opens, and the mouth of the pitcher is exposed to view. The color is pale green, but often tinged or spotted with red and purple.

From the Field Naturalist.

THE LLAMA OF PERU.

We are indebted to the attention of a correspondent in Oban for the following account of the interesting attempt now making in that neighborhood to domesticate the llama.

I am not surprised that the llamas here should be exciting attention, for they certainly are objects worthy of notice. This animal does not in any shape resemble the sheep of this country; its height is from four to five feet, with long legs and long neck, in some respects not unlike the camel, a small head without horns, the countenance gentle and expressive of wonder. It is not remarkable for any peculiar habits, except that it delights in ascending to the summits of the hills: its appearance indicates an unfitness for climbing: I observe, however, nature has served it with a hooked claw on each hoof, which enables it in some measure to travel heights with as much security as the goat. Their food and treatment differ in no particular from Mr. Stevenson's cows; they graze, eat hay, chopped straw and potatoes, with them daily, and have formed such an attachment to the cows, that when the latter are brought from the hill for the purpose of milking, the llamas will not remain behind, but accompany them to and from the byre three times a day, a distance of half a mile—the wool is extremely fine, each fleece weighing from five to six pounds. Mr. Stevenson imported the first pair (of the Alpacha breed, for there are several varieties,) about three years ago—he tells me that there were four or five pairs shipped for him, but all died during the voyage except the one, and the following year he received another pair of what he terms the real llama, but a common observer cannot descern any difference. They inhabit the mountains of the Andes, and, when domesticated, are used in that country as beasts of burden, chiefly in carrying ore from the mines of Peru, and they carry about 100 lbs., and if one pound be added more than they can carry with freedom, like the camel, nothing will impel them forward. If there was any chance of rearing them, they would doubtless become a benefit to the country, but I fear the hope of their breeding is very uncertain.

From the Arcana of Science.

SOLVENT OF INDIAN RUBBER.

There is no solvent of Indian rubber so good for gardening and most other purposes, as refined coal tar, sold under the name by drug merchants, which is only common coal tar deprived of water by boiling.

From the Southern Agriculturist.

ON THE PREPARATION OF VEGETABLE OILS.

The production of the fixed vegetable oils, has in all climates been a source of wealth; and of course has attracted the science, industry, and capital of cultivators. The plants in use are confined to no zone, though growing in greater variety and abundance, in tropical or hot countries.

We, too, have indulged in speculating upon the agricultural value to us, of oil plants. These speculations have been generally discursive, or directed to some individual of the class. The only methodical investigation of oil-bearing plants, known here or easily introduced, of which we have ever been informed, was undertaken by the late Mr. George Trescot, in whose education, the exact sciences preponderated so much, as to impress us with the belief, that his inquiries would be valuable for their order and precision, he had, as we learnt, in conversation, made considerable progress in his researches, but his untimely death, it is presumed, left them imperfect.

In the east, the plants cultivated for this use, are mustard, the fixed oil of which is as mild and bland, as the volatile oil is notoriously acrid; linseed, familiarly known every where. Sesamum and Palma Christi. This last has been successfully cultivated in all parts of South Carolina, the oil commanding a higher price in the market than any imported. The mode of extraction was generally by boiling. It has fallen into disuse, unable to compete with the profits of our cotton culture, and perhaps, in some degree, from the difficulty of the harvest: the seeds ripen successively, and are shed by the plant as they mature, the loss in this way bears heavily upon the whole crop. It is cultivated like Indian corn, but we are without any circumstantial estimate of the expense and profit of growing it. Many gentlemen resident near Beaufort could supply this estimate, and we hope to draw the attention of their agricultural associations to it.

The sun-flower seed is used in a limited degree in Europe, from the Spanish peninsula to Russia, and its cultivation has been earnestly recommended in the United States, where, in some instances, it has produced 60 or 70 bushels to the acre, the bushel yields three quarts of cold and one of hot pressed oil. Notwithstanding the plausibility of this account, we know of its growth only to feed poultry, and especially turkeys, which thrive upon the leaves and seeds, and, perhaps, it is used quite as much for the pleasure of its flaunting flowers, as for any profit which it brings.

At Arras, and other places in France, extensive tracts are covered with poppies, which adorn hill and dale with their rich variety of bloom. These are intended to produce seed only, and large mills are erected to crush and press the oil from the seed. When first pressed the oil is colorless and insipid, and the avowed object is to adulterate with it, the more costly olive oil. The same cultivation prevails in Flanders.

All plants producing oil exhaust the fertility of countries in which they are extensively grown, and in fact, they will grow thriftily only in the richest soils. At the mention of exhausting plants, the memory of every reader promptly recalls the cotton, now about to derive from its seed a new recommendation.

A mill for preparing the cotton-seed oil, was erected at Petersburg, in Virginia, several years ago, by Follet & Smith, patentees of that part of the apparatus intended to hull the seed. This process was considered indispensable, and the owners of the patent-right set upon it so high a value, as to deter from the general adoption of it. A small establishment on their plan was made in North Carolina, and General D. R. Williams, of Society Hill, in South Carolina, is believed to have erected a mill after Mr. Smith's plans: we should be glad to hear the results from our friends in that quarter. In order to bring their mill into prominent notice, Messrs. Follet & Smith obtained from our legislature an act of incorporation for a Joint Stock Company, to hull cotton-seed and press oil, but the project has not excited attention, and seems likely to rest in the hands of the patentees.

Launcelot Johnson, of Georgia, invented an instrument for hulling cotton-seed, which he describes as a truncated cone, furnished with teeth, which revolves in a tub adapted to its form, and also furnished with teeth; the two sets of teeth pass near each other and tear off the hull, this is separated by a sieve and fan from the kernels, and the kernels are pressed. One thousand pounds of upland cotton will produce twenty-five bushels of seed; three bushels of seed produce one of kernels, and one of kernels produce two gallons of oil, or one and a half to two bushels of seed, will produce one gallon of oil. This contrivance has not been patented, but on the contrary, the most liberal offers of its use extended through the public prints, with the earnest recommendations of the Hon. Mr. Clayton of Georgia. It has the appearance of a cheap, easily managed, but imperfect engine, and other means supposed to be more efficacious have been adopted.

Individuals in New York are known to use methods of expressing and purifying cotton-seed oil. And the Messrs. Freemans, of Philadelphia, extract the oil without hulling, and clarify it very perfectly; their methods are, we believe, secrets of trade.

Messrs. Plummer & Miller erected in 1833, a very extensive mill at Natchez, moved by a powerful steam engine, and brought to this enterprise all that capital and organized labor can provide for its perfection, their mill has been in profitable operation ever since, and they have secured the most perfect means of purifying their oil. We learn from a traveller, that they have been joined by James H. Couper, Esq. of the Alatamaha, and to those associates, an act of incorporation was granted during the last year, for half a million capital, the establishment at Natchez, being rated at $100,000 in stock. Steamboats ply up the Mississippi, and its tributaries for the collection of seed, the rank fertility of the soil makes this of no value as manure; and it is obtained in part, at least, for the labor of its removal. Branches of the Natches' mill, have been and will be extended through that country.

Mr. John Couper, jun. of Georgia, is the proprietor of a mill of considerable extent at Mobile. His oil when purified by processes, lately introduced, sells there at 90 to 120 cents a gallon.

Cotton-seed oil is consumed, *in painting;* in this use, its character is that of an oil drying very slowly—more slowly than linseed-oil, and unless purified, darker in color; in *burning*, in this, it produces no effluvia and little smoke; in *manufacturing woollen cloths*, in this, its value seems yet uncertain, indeed, very doubtful. For *machinery*, where we should suspect it of too great a tendency to become inspissated, though they say not; and in *adulterating* castor oil, for which it is recommended as a mild substitute.

The meal or oil cake has great value in feeding stock, even hogs partaking of it without injury, the removal of part of the oil, and perhaps, the hull render it more digestible than before. Negroes employed about the mills frequently mix it with their corn-meal as a savoury ingredient; and we have been assured by an eye witness, that it is a decided improvement.

It does seem strange that this state should be the most tardy in turning to account a very valuable product. At length, however, if we are not misinformed, one of our skilful and wealthy planters, is about to embark in the business of pressing and purifying cotton-seed oil here at home.

We solicit from our distant readers intelligence upon this subject.

CONDUCTOR.

From the Arcana of Science and Art, for 1835.

AFFECTION AND VAST NUMBER OF FISHES.

* * * * *

But affection is scarcely to be looked for where the offspring is so very numerous as to put all attempts at even recognising them out of the question. How could the fondest mother love 100,000 little ones at once? Yet this number is far exceeded by some of the matrons of the deep. Petit found 300,000 in a single carp; Leuwenhoeck, 9,000,000 in a single cod; Mr. Harmer found, in a sole, 100,000; in a tench, 300,000; in a mackerel, 500,000; and in a flounder, 1,357,000. M. Rousseau disburthened a pike of 160,000, and a sturgeon of 1,567,000; while from one of this latter class, some other person (whose name we do not immediately recollect,) got 119 pounds weight of eggs, which, at the rate of seven to a grain, would give a total amount of 7,653,200 eggs! If all these came to maturity, the world would be, in a short time, nothing but fish; means, however, amply sufficient to keep down this unwelcome superabundance, have been provided. Fish themselves, men, birds, other marine animals, to say nothing of the dispersions produced by storms and currents, the destruction consequent on their being thrown on the beech and left there to dry up, all combine to diminish this excessive supply over demand. Yet, on the other hand (so wonderfully are all the contrivances of nature harmonized and balanced,) one of these apparent modes of destruction becomes an actual means of extending the species. The eggs of the pike, the barbel, and many other fish, says M. Virey, are rendered indigestible by an acrid oil which they contain, and in consequence of which they are passed in the same condition as they were swallowed, the result of which is, that being taken in by ducks, grebes, or other water fowl, they are thus transported to situations, such as inland lakes, which, otherwise, they could never have attained; and in this way only can we account for the fact, now well ascertained, that several lakes in the Alps, formed by the thawing of the glaciers, are now abundantly stocked with excellent fish.

A METHOD FOR THE DESTRUCTION OF THE CUT WORM.

To the Editor of the Farmers' Register.

Ben Lomond, Aug. 3, 1835.

It is doubtless a subject of interest to the farmer to be informed on any subject relating to his advantage; and as your periodical has for its object the improvement of agriculture in all its branches, I willingly contribute my *quota*, hoping that what I may say, may serve in a measure to aid that object.

There was a field brought into cultivation this spring which had not been cultivated for several years. The crop planted was corn. The corn sprang up, and had begun to grow "pretty considerably," when on examination a few days after, it was discovered that most of the corn was entirely destroyed by the cut worm. Corn was again planted, and still the same case continued, until in that field the corn was (I may say) planted entirely three times. By accident, however, a small portion of the grass had been burnt—and on examination it was observed that a very small portion of the crop required "*re-planting*," (as the farmers say,) from that cause, viz: cut worm. In this case the cut worm was destroyed, doubtless by the fire, as it was destructive to all parts of the field, except the part burnt. Then, if you should be troubled, or rather expect trouble from the cut worm, if you will burn the grass on your lands, I think I can safely guarantee to you, that the destruction of the worm will be sure.

If any of your readers are willing to profit from the experience of others, let them when necessity requires, try the remedy, and effect the cure.

F. B. WATKINS.

SCARLET TREFOIL. SPECULATIONS ON THE PECULIAR BENEFITS TO WHEAT OF A PRECEDING CROP OF CLOVER.

[The following extract is from a late English pamphlet entitled *Further observations on the cultivation of Scarlet Trefoil, &c.* The facts stated are interesting and important—and though the reasoning is far from satisfactory, it may furnish subject for thought and more successful deductions, on an important and mysterious breach of husbandry, viz. the growth of wheat after clover, and the peculiar benefits furnished by the latter as a preceding crop.]

Now turn to the scarlet trefoil;—whether cut green for the horses or cut for stover, it may be clear from the land the first or second week in June; then the first time the plough goes into the earth it turns up like the finest garden mould, it is like ploughing an ash heap, or diving into a barrel of flour. In the same field, one part of the land is all powder, with only one ploughing, before the harrows have even touched it: and by or before the first of August it will be in a better state than the fallow, where the farmer has been rending and tearing to pieces his implements of husbandry, and wearing his horses to skeletons. The benefit will not end here, for where the scarlet trefoil has grown, the succession crops will be better than on the fallow; I have invariably seen it.

It is impossible to know and contemplate these circumstances without being led into further reflections upon them; in hinting at causes that may produce these effects, it is solely done to ask for information, trusting that this pamphlet may stray into the hands of the scientific, as well as the agriculturist.

When we consider the living wonders contained in a drop of water, which the microscope has lately brought to view, have we not reason to suppose that a grain of earth may be equally teeming with animal life; and when sheltered and protected from the sun's scorching rays by the scarlet trefoil, may they not have produced the effects I have mentioned, and which absolutely hold up the boasted arts and labor of man to derision?

It is well known to every farmer, that when he has a field of clover, part of which shall be a perfect full plant, and part without a leaf upon it, and this last shall be kept free from weeds the whole summer, the other part mown twice, and all the produce carried off the land and nothing returned, yet where this land has been thus robbed without rest or manure, the farmer well knows that the following year this very land will produce him from seven to eight sacks of wheat per acre, and the part that has had perfect rest will not produce three.* Ask a farmer the cause of this, and he will tell you because the earth has been exhausted by the sun: ask, exhausted of what? and after being posed for a time, he will say—moisture: the farmer may be right; I think exhausted of animal life. The farmer well knows if this land is broken up by the plough—the harrows and rolls set to work upon until it is reduced to powder, the moisture will be still further exhausted, yet it will be equally fertile with the other for his crops in due season.

Have not agents, unseen, been doing this work beneath the shelter of the clover, which the farmer knows he must do with his ploughs and teams, to make his land productive? I could mention numerous other circumstances which appear to point the same way.

---

* The first part of this sentence is either written or printed very incorrectly, but the intended meaning is easily gathered from the remainder of the passage. The author evidently designed to compare the results of wheat on clover lay (though after mowing,) which in this country is called "fallow," with the very different preparation for wheat called "fallow" in England.—ED. FAR. REG.

There is a phenomenon frequently occurring in our fine autumnal days, which creates a moment of pleasure and surprise to the traveller. In less than two hours after the plough has turned up the furrows of a field, it will be completely covered, as if a sheet of gauze or lawn had been cast over: this is known to be the work of countless millions of a small species of spider, which are never seen till the plough turns them up to the light. We cannot believe that the Almighty Creator of the universe can have formed these little artizans, solely that the mind of man may receive a moment's pleasure from viewing their floating gossamer.

The information I seek comes, as a question, into a small compass: To what extent animal life exists in the earth, and how far vegetation depends upon it?

From the Southern Agriculturist.

THE FIG, (*Ficus Carica.*)

A native of Caria, in Asia, whence its name: known in the warm climates of Europe and Asia: in its wild state bearing fruit; perfect in the developement of the parts of fructification, but without flavor; those in which the stamens are most conspicuous are apt to fall before maturity, and are used to impregnate and accelerate the ripening of cultivated figs. The practice is said to prevail under the name of caprification, and has given rise to the controversies among travellers in the Levant. The only inaccuracy fairly chargeable upon those who assert the existence of the custom, is perhaps, an affected exactness in the details described: and some extravagance in the results attributed to it. The practice occupied more attention than its importance would seem to have warranted, and has now become a mere matter of curiosity.

Other modes of forcing the fruit to maturity are said to have consisted in punching the fruit at the flower end, or inserting in that end a drop of oil.

This use of oil has been made familiar to us by experiments at home; in our 4th volume, page 224, the use of olive oil or hog's lard in Florida, is described as ripening green and hard figs in seven or eight days, several weeks in anticipation of the regular period of maturity. At page 388, several members of our Horticultural Society concur in stating that applied to the flower ends of fruit from 1 to 1½ inches in diameter, ripens them fourteen days earlier; that oiling the whole fig was injurious; and that the use of oil to those less than one inch in diameter, caused them to fall off, without coming to maturity. At page 473, a drop of oil was applied to the centre of the flower end of the fruit, in less than 24 hours the fruit began to swell and matured a fortnight earlier than those without oil. At page 534, there is reason to believe that the limit to a beneficial use of oil, is in anticipating by seven or eight days the usual time of ripening. The fruit touched at an earlier growth either fell off or was insipid, olive oil or sunflower oil were found effective, tallow and lard ineffective; the trial was extended to both black and lemon figs. At page 582, its mode of operation is discussed, which seems to be by arresting the growth of the part touched, and giving to other portions of the fruit extraordinary stimulus.

We delight in this fruit, and remind our friends of the results recorded as an introduction to what we now propose.

Although one or two doubtful cases have been mentioned to us of the growth of seedling trees here, we think ourselves safe in saying, that no other mode of propagation is known to us, but by cuttings, layers, or suckers.

Many varieties are cultivated here, and of each variety, there are great differences observable in the quality of fruit from individual trees. We propose that every person possessed of a peculiarly fine tree, should take note of its production, and enable us to record a description of the tree and its locality, with a view to the extension of its culture.

The storm of 1822 blew down a tree so large, that it could not be replaced without cutting off its branches; these were trimmed very short, and the tree erected, put forth a vigorous growth of wood. The next year the fruit was so much larger and richer in flavor, as to induce this resolution, of three trees, to cut one close each year, and thus secure a constant supply of fruit from young wood upon large stems; the suggestion is thrown out with the hope of provoking trials to be communicated to us hereafter. The three following sorts are not known to us, and if they exist here, we should be glad to hear of them.

Large white Genoa, fruit large, pale yellow without, red within.

Brown Turkey, large, reddish brown.

Black Genoa fig, fruit purple, almost black, large at the flower end, becoming slender at the stalk, downy and colored like a rich plum.

In the garden of Mrs. Wagner, St. Philip's-street, there existed last year, a very fine tree, suspected to be a brown turkey fig, we hope to hear that it escaped the frost, and recommend it to our readers.

Our people are not sensible of the value of this luxury, or of our peculiar advantages in its cultivation. The following passage will enable them to compare the ease with which we produce this salutary and abundant fruit, with the pains taking of French gardeners.

"The inhabitants of Argenteuil, near Paris, derive their chief support from the culture of fig trees; near that town are immense fields covered with these trees, on the sides of hills facing the south, and in other places sheltered from the north, and the north-west winds.

"In the autumn, the earth about the roots of these trees is stirred and dug; as soon as the frosts commence, the gardeners bend down the branches, and bury them under six inches of mould, which is sufficient to preserve them from being frozen.

"The branches must be entirely stript of their leaves before this is done; the gardener then taking hold of the top of each branch, bends it down gradually, and with much care, to prevent its breaking, placing his knee or hand under such parts as resists the most; the branches that will not bend low enough to be buried, are cut off close to the ground.

A fig tree will remain buried in this manner seventy-five or eighty days without harm; when the season is mild, the gardeners uncover them, especially in times of warm rains, but on the first symptoms of frost they are again buried. Severe frosts sometimes reach them, but the branches only are destroyed. The roots produce a new crop in the summer; but these do not bear fruit till the next year, and are more tender and liable to be killed by frost during the next winter, than older and more woody branches.

"In the spring, the trees are carefully inspected, and where a double bud is observed, the gardeners, who are able to distinguish a leaf-bud, which is more sharp, from a fruit-bud, which is rounder, pinch out the leaf-buds, without hurting the fruit-buds; these, as they receive the sap prepared by the plant for two purposes, produced fruit of double the ordinary size: this is done at Paris between the first and tenth of June: but these leaf-buds may be suffered to expand a little, till they can be distinguished with certainty: they must not all be destroyed at the same time. In cold seasons, the ripening of the fruit is hastened by inserting a drop of oil in the eye, from the point of a pen or tooth-pick.

"It is necessary in dry seasons to water fig-trees: the nature of the plant requires to have its roots cool, while its head is exposed to the hottest sun. If planted against the south wall of a house near a spout that brings water from the roof, it thrives luxuriantly. Figs do well also in a paved court: the stones keep the ground under them moist and cool, while the surrounding buildings reflect and increase the heat of the sun's rays."

From the Genesee Farmer.

LATE MOWED HAY.

The editor of the Western Farmer has objected to our recommendation of mowing after harvest. We hope he may be enabled hereafter to make more accurate observations.

In our youthful days, it was the practice to mow the natural grasses as soon as might be after they came into bloom. The hay was of a beautiful green; and all persons, as far as we knew, thought it must of course, be the best. About twenty-five years ago, our attention was first turned to the subject. Farmers in this quarter, cut their grass at such times as were most convenient; that is to say, a part was generally cut before harvest; but the principal part, owing to the pressure of other business, was cut after the grain was secured; and the same motives of convenience induced us to adopt the same practice. We found however, by repeated observations, that our live stock, whenever they had the liberty of choosing, rejected the green hay, and preferred that which had been well matured, although of a rusty appearance.

Having clearly ascertained the fact we inquired of some of our most intelligent farmers who were also acquainted with the value of well ripened hay, what was the cause of this preference? and the purport of the answer we received, was as follows: "Grass cut before it is matured, contains little or no saccharine matter; the juices turn sour, like wine that is made of crude or watery grapes; and the sense of taste in chewing two stalks of two kinds can distinguish them at once—the one being much more sweet and pleasant than the other."

The notion that plants are always nutritious in proportion to their quantity of soluble matter, is erroneous. The quality of that matter, is of more consequence. Sugar is supposed to be more nutritive than any other substance; and no plant has yet been discovered that produces it in such quantities as the sugar cane. This is one of the natural grasses; and it is only cut when the plant is mature. Indian corn is also one of the natural grasses, and its stalks yield much saccharine matter. In the revolutionary war when our intercourse with the West Indies was interrupted, many families were supplied with molasses obtained from this plant, but the stalk was always used when it was well ripened.

The leaves of the cane are entirely rejected in the manufacture, as the sugar is not deposited in any part except the pith: and the last remark will apply to plants of Indian corn. Sugar is also obtained from the pith of the Bamboo, another of the natural grasses. We mention these things to show by analogy that the dried leaves of timothy may be of little value, and the deterioration, if any, is not then to be imputed wholly to the increase of saccharine matter in the stalks.

We are not prepared to say that the artificial grasses yield sugar in any valuable quantities; or that the plants should be well ripened before they are cut for hay. At present we rather incline to the opinion that a distinction in this respect ought to be made between the two natural orders: and that the latter may not be improved by standing very late in the season.

From the New York American.

COOKING BY GAS.

This new application of gas seems to us of great promise, for economy, comfort and safety. We had heard nothing of it until a few evenings since, on the invitation of Mr. *J. [illegible]*, president of the Manhattan Gas Works, we had an opportunity at his house, both of seeing the process in operation, and verifying the fact that what was there cooked, was "well done," even though not "quickly done".

The apparatus is of great simplicity. A circular or eliptical burner of such dimensions as may be needed—in a large family several of different dimensions would be required—is constructed, pierced with numerous and very small apertures, so that all the gas that passes may certainly be consumed. In the centre of the circle, is a permanent perpendicular spit, on which the joint to be roasted is impaled, a sheet iron funnel-shaped chimney, large enough at the bottom to include the lights, and tapering upwards so as to concentrate and reflect the heat, is then placed over the whole, and the cook may go about any other business, for the next two or three hours, fully assured on coming back at the end of that time, of finding the meat well cooked. But this is not all. Over the funnel-shaped chimney is placed a large tin vessel divided horizontally into two compartments—the lower one serving as a kettle to boil water, the upper as a vessel in which to boil meats or vegetables, and the same fire and the same time required for roasting, will also suffice for boiling the water, and cooking the vegetables. The cost for fuel of such a fire, as we saw, by which a 12lb piece of beef was roasting, was stated by the superintendent, Mr. *Barlow*, at two cents an hour—or six cents for the whole period for cooking dinner—add to this the further economical advantage, that you only light your fire when you want it, and extinguish it the moment it has fulfilled its purpose, and we have a strong argument on the score of cheapness.

It is obvious that any number of these burners may be arranged—all to be supplied by one main leader—and as the cost of these fixtures is small, and only the gas actually used is paid for, it would be expedient always to have several of them.

Of course the value of this new application of gas depends upon proper care in the use of the apparatus, and on the part of the company, in the preparation and purification of the gas. As to the first, the whole thing is so simple, that except through wilfulness there could be no mistake, and as to the purification of the gas, the interest of the company would be so great in seeing to that, as upon its fredom from smell and brightness in burning, its general use would essentially depend—that little need be apprehended on that score.

Upon the whole we confess ourselves amazingly taken with this kind of fuel—and recommend to our friends to ascertain, at the works of the Manhattan Gas Company, the cost, and the advantages particularly in hot weather, of such kitchen fires.

For the Farmers' Register.

ON DRAINING, AND RECLAIMING LANDS, SUBJECT TO INUNDATION FROM FRESHETS, BY DIVERTING, AND STRAIGHTENING THE BEDS OF STREAMS.

The figure in view, exhibits a body of creek low grounds, drained and reclaimed from freshets, in which

A F C D E represents the channel of the creek.

A F C the part of the old channel to be changed.

A B C the new channel, cut through the middle of the low grounds.

G H I J K L M, a margin ditch on the border of the first low grounds.

S, S, S, S, &c. ponds, drained in different parts of the low grounds.

t, t, t, &c. little ditches, many of which rendered useless by the main drain.

O P Q R, a conductor at the foot of the hill, at the border of the second low grounds.

T U V W X Y, outlets from the conductor into the margin ditch.

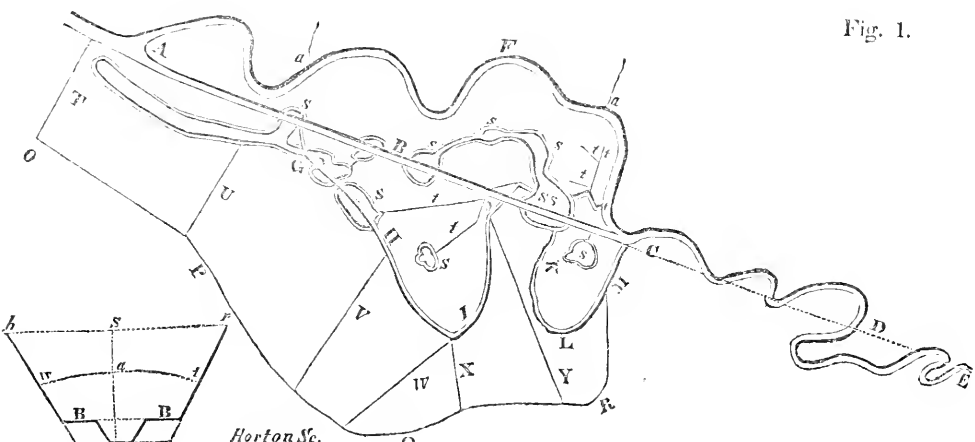


Fig. 1.

Fig. 2.

Having explained the general features of the figure, the remarks which accompany it we shall briefly arrange under three heads.

1*st*. The *condition* of the land exhibited in the above figure, before drained and reclaimed.

2*nd*. The method adopted to effect it. And

3*rd*. The effects produced afterwards, and the advantages derived to the land, from the whole operation.

First then in regard to the *condition* of the land. It was very subject to *inundation*, so that in extraordinary freshets, the low grounds was for the most part covered with water. Secondly, it was in many places excessively wet, being constantly saturated, and often supersaturated with water, oozing out and coming down from the adjacent hills: for the flat being so wide and level, there was no way of getting rid of it except by evaporation. Thirdly, it was subject to continual washings and scourings, occasioned by the stream cutting across the bends of the channel; which washed and gullied places being abandoned, became stagnant ponds that grew up in bushes, and offered a safe retreat for the nursery of black birds, that are more destructive to the young corn than even the freshet itself. Fourthly, the land was inconveniently intersected with a number of small ditches, the birth-place of bushes, and obstacles to the plough. Fifthly, the land was frequently worked out of season, from being too wet at the proper season. Sixthly, it was liable to be worked wet, and when so, the invariable consequence was, a diminution of the crop; impoverishment of the land; increase of draught on the horse; and the land was cloddy all that season. Seventhly, the land was so wide and level, that there were few outlets for the superfluous water, except the old channel: and that frequently at so great a distance, that the ditches necessary to conduct it off were too long, and of course liable to fill up, and too expensive to cut. Eighthly, pasturing the land in this condition was extremely detrimental, and it must be pastured so, or not at all, frequently. The pasturing of lands in wet weather, especially in long rainy spells, must be very injurious to them, especially arable lands. Cattle, it appears to me, should be kept up during such spells. Lastly, the low grounds were disfigured, with many undrained ponds, sunken places, &c., the effluvia of which, is generally unfriendly to health; though I have never suffered from this cause, the ponds being of small extent. Such was the condition of the land, which leads us to consider

Secondly—The method adopted to drain and reclaim it from inundation.

To do this, I diverted the part of the stream A E C, from its ancient bed, through the heart (or belly rather, of the low grounds, as it now answers the purpose of a main gut, or as physicians would say, the alimentary canal) into a new channel A B C, ten feet wide, and on an average of four and a half or five feet deep, and about three quarters of a mile long. This depth however, was found insufficient; and then I had a small ditch excavated, in the middle of the bottom of the big ditch, three by two feet deep. This gathered the water into a deep, narrow channel, which increasing the velocity of the stream, soon by its abrasions, ripped up the adjacent benches, B B Fig. 2, (which represents a transverse section of the canal, down to the bottom of the little ditch *o*.) The ditch has washed out in width and depth astonishingly, since it was cut, contrary to the expectations of many persons, who supposed that the land being so wide and level, there was little or no fall, and consequently the channel would not wash sufficiently, to take the stream in high water. It is now from 40 to 50, and in some places 60 feet wide, and upon an average of six and a half feet deep: and where it passes through knolls, eight or nine feet in depth. There are holes in the bottom ten feet deep; but this is not the uniform depth of the bottom. I observe that the clay parts of the ditch wash more, and more uniformly, than the sandy parts, contrary to the common opinion. The reason for this is obvious. The clay parts of the ditch are less encouraging to vegetation, than the sandy parts; the grass and weeds springing up from which, catches the trash and sediment, and further promoting the growth of weeds and grass, the roots of these hold the banks of the ditch together, and prevent their being washed away. In dry weather too, the clay cracks in large fissures, and when a freshet occurs, the water rising and running into these chasms, sever large blocks of clay from the banks, which tumbling in the water in a dry state, soon dissolve and wash down the current. These lumps leaving scooped places in the banks, the large projections of earth above also tumble in, and dissolve away. There is another reason: the clay freezes in the winter when the water is down, which pulverizing and loosening it, gives the water a prodigious effect on the banks. If there is much fall at the sandy places, then they wash very much; otherwise they do not: for the vegetation then has no time to cover the banks, the sediment being washed away as fast as it accumulates.

In cutting this ditch, it will readily be seen, by looking on the figure, that the current in the old channel is not diverted from its general straight course A B C D E, (which is uniform in all streams that flow in a certain direction towards the ocean, for however they may meander in particular parts of their beds, they have in the main a straight course,) but only diverted from a part of its old bed, A B C D. On the contrary, the stream is directed more into its general straight course, (which is here southerly,) as the figure shows; for if it were continued where it now runs, above and below, it would be in a right line, with it's natural direction, A B C D E; so that it may be considered as only cutting off a large bend or elbow of the creek, about a mile and a half long, following in the measure, all the curves of the old channel. There is much evidence to believe that the stream was once more in this general straight course, (to which attention should be paid in straightening channels,) than when it meandered along the foot of the hill, from whence it has been lately diverted, since the canal now passes through many places which appeared to have been once ponds, (but were entirely filled up when the ditch was cut, with sand, leaves, and rotten wood, as far down as the bottom of the ditch,) no doubt formed by deserted parts, of a very ancient channel, from whence the current must have receded towards the foot of the hill, where it formerly ran; that is, along A B C D. This recession in streams, from more elevated to lower places, is occasioned by the current itself, gradually raising, by depositions of mud and sand, the banks of its channel, above the adjacent ground, (hence the bed of a creek or river lies oftentimes in the highest part of the low grounds,) where if it meets with obstructions, it retires with the fall into the low places, and following the indentations, or natural sinks of the land, it forms numerous curves, and becomes extremely crooked, till the foot of the hill fixes a limit to its further mutation, at least for a time; but as its banks here become higher than the surrounding land, it changes again to the same place probably, from whence it first was diverted.

The clearing and cultivation of land, has had a powerful influence on the mutation of the beds of streams. Subsequent to these operations, the channels of streams have become much straighter, less branching, (that is, the water collected more into one main channel,) and the banks have become much better. By felling the timber, and loosening the soil of the adjacent hills, many ponds and sunken places have been filled up in the low grounds, with the sand and soil washing down from thence; and the streams too, being loaded during freshets, with sand and mud from the same source, have filled up the holes they formerly made, and the parts of the crooked channels they have deserted, and have formed by their increased velocity, and the sediment they deposite in freshets, new and straighter channels for themselves, and higher banks. The executor of the work under consideration, a very intelligent man, and one of observation, and who had had 50 years experience on the subject of mill races, and straightening creeks, observed to me, that before the country was much cleared, when he first turned his attention to the subject of ditching, the streams, where the low grounds were wide especially, divided into numerous branches, and ran in many places, nearly over the whole low grounds, in so much, that it was oftentimes difficult to distinguish where the main current flowed—that the that lands were more indented with ponds, and disfigured with quagmires, than at present. This cannot be ascribed to ditching and draining of low grounds of late years altogether, (for although ditches drain ponds, they do not fill them up, unless a constant current passes through them,) but is owing chiefly to ploughing the hills, and removing the trees from the low grounds, by the trunks of which, the current is divided into numerous channels, and around the roots of which deep holes are scooped out, to the great impoverishment and disfiguration of the land.

At the termination of the ditch C, there is an excellent draw-off for the water; (which is very important in an effectual piece of work of this kind) the old bed of the creek being there wide, and nearly straight for a considerable distance: it is also straight above, at the upper end, which affords a good inlet, which is also very essential; so that the water has a straight course now for about a mile and a quarter, without obstructions. Any one may see at once the advantage of a continuation of the new channel below, and from the crookedness of this part of the creek, may form some idea of the necessity of straightening the natural beds of streams in general; for which purpose, this part of the old channel was appended to the figure. Though my land below this point is very little subject to inundation, except immediately on the bends of the creek, it being for the most part what is called "seconds," and of course out of the reach of freshets. The advantages derived to the land below, by an extension of the ditch, might not justify the expense, unless combined with those resulting to the low grounds above, where the effect would be greater. These two considerations jointly, might justify perhaps, a continuation.

In regard to the execution of the work under consideration, it does not differ materially from what is in common practice. Figure 2, is designed to exhibit at once, the manner of excavating the earth, in cutting the ditch. It represents a transverse section of the canal: *h* and *p* represent the sides of the canal; B B the bottom; *h s p* a line drawn across the top to measure the ditch; *s a o* a plumb line dropped from this to measure the perpendicular depth of the ditch: *o* a section of the little ditch, cut in the middle of the bottom, B B, of the canal. The object of cutting a canal of this sort, that is to contain and carry as much water as possible, depends on the *form* of this figure, for the *velocity* on which the *washing* and *quantity* of water carried depends on it. The velocity depends upon the narrowness of the bottom: but the narrowness of the bottom depends (the width remaining the same) on the inclination of the sides, or the angle they make with the bottom; therefore the velocity is as the inclination of the sides: but the action on the sides and bottom depend on the velocity, therefore the washing depends on the narrowness of the bottom. So that it appears that if the form of the figure was altered in such a manner as that the sides would meet in an angle at the middle of the bottom of the ditch, the velocity of the water would be greatly increased. But as this could not be practised in so large a ditch, the sides ought to slope in such a manner as to make the bottom not more than a fourth of the width of the top. But it must be observed, that if the velocity of the water depends on the inclination of the sides, the caving, which is a consideration, depends on their perpendicular form; so that the ditch ought to be cut in such a manner as to combine the two advantages derived from caving, and increased velocity of the water. The fact that the same volume of water would run swifter by diminishing the width of the bottom, induced me to collect the thin sheet of water running on the bottom B B of the canal, into a channel with a narrower bottom, *c*. But the effects produced by admitting the current into the new channel, we shall notice more particularly hereafter, my object here being simply to show how the work should be executed, without entering minutely into the reasons for it, or to enumerate the advantages derived from it, which come more properly under our second division of the subject. The mouth of the ditch should be cut wider than the other part of it, for 50 or 100 yards down—and a stop made in the old channel. The next means adopted, in point of importance to the canal, to drain the land in question, was the cutting of the margin ditch, and other smaller ditches and conductors, already mentioned, a better idea of which may be had by looking on the figure, than by any verbal description, which would be unnecessarily tedious—when our object is brevity, without leaving out essentials. Sufficient allusion however will be made to them to show their design and importance in the figure, as we pass on.

Having pointed out the method adopted to drain and reclaim the land, we proceed—

Thirdly—To show the effects produced by straightening the old channel, and the advantages derived to the land through which it runs. Besides other advantages which we shall hereafter enumerate, the two principal ones, in view of which the work was undertaken, were completely obtained: that is, a thorough *drainage of the land*, and the *reduction of freshets*.

The manner in which the ditch operates as a drainer, and its absolute necessity in this body of flats, to drain it effectually, will be first pointed out. What renders it necessary to drain a body of land of any description, is the redundancy of water, over what is necessary of that element, for vegetation. This is of three sorts: rain, spring, and pond waters; but as ponds are collections of rain or spring water, they may be reduced to two only. The method which has been adopted to get rid of these, when in excess, is called draining. The aqueducts generally necessary to drain a body of flat land, are eight in number: the main drain, or "main carrier," as it is sometimes called, (a term borrowed from the irrigation of land,) margin ditch, surface ditches, grips, trenches, or what are commonly called water-furrows, pond ditches, pits or perforations, and hill-side trenches, (usually called conductors,) though every ditch, or trench, which carries water is properly a conductor. The main carrier, is a large ditch cut through the middle of the low grounds, the object of which is to intersect all the subterranean passages of water, or veins, that it may flow off, and to answer the purpose of an outlet to the water, more particularly of the margin ditch. The margin ditch is generally a crooked conductor, opened either at the seam of the first and second low grounds, or at the foot of the hill, at the margin of the first low grounds; the object of which is, to receive the water of the surface ditches, and hill-side trenches, and to empty it into the main carrier. Surface ditches, as called from their design to take off the rain water from the surface, are generally cut with a spade, either obliquely (with the *fall*) or at right angles to the margin ditch, and frequently to the main carrier, the object of which is to receive the water of the grips, and to empty it into the margin ditch. The grips are cross furrows, made by the plough and hoe, along an indentation across the beds, the object of which is, to receive the water of the trenches, or water furrows, and to empty it in the surface ditches. The trenches, or water furrows, are made with the plough, and scraped out with the hoe between the beds, and are designed as a receptable of the water which falls on the beds, and to empty it into the grips. Pits, or [illegible], are holes made with the spade, or bored into the ground to sink the water by some subterraneous passage, when it is retained by a stratum of clay, when there is no convenient outlet for a ditch, usually made in basins or ponds. When the stratum of clay is cut through, the water sinks into the land. Places have been drained in this way, where success could not be had in any other. Pond ditches are those which are designed solely to drain off pond water, and should always be cut through and below the bottom of the pond. Hill-side ditches or trenches, when made near the foot of the hill, are designed to take the water which falls on the hill-sides, and tops of the hills from the flats, and to convey it by outlets, as in Fig. 1, into the margin ditches; so that the water which at first falls on the surface of the beds, runs into the water furrows; out of the water furrows into the grips; out of the grips into the surface ditches; out of the surface ditches into the margin ditch; out of the margin ditch into the main carrier; out of the main carrier into the old channel; out of the old or natural channel, into the ocean. But the farmer must not think that now he has gotten entirely rid of his superfluous water—that it is gone forever, and lost in the ocean. Though but a drop in that "bottomless abyss," it will come back again, it may be the very next day, in the form of drops falling on the very spot from whence it started. "The sun riseth, (saith the wise man) and the sun goeth down, and pants for the place from whence he arose. * * * All rivers run into the sea, yet the sea is not full. Unto the place whence the rivers come, thither they return again." Out of the ocean it goes into the air, drawn up in exhalations by the heat of the sun. (or rather the heat removing the pressure of the atmosphere on the surface of the ocean, the water rises, being divided into small particles by absorbing heat, by its specific levity into the air:) out of the air it goes into the clouds, or rather it assumes the form and appearance of clouds; clouds being nothing more than these watery particles made visible by becoming denser. Then comes the wind, and blows them back over the place from whence they came, and being condensed by cold (the absence of heat) and by gravitation, are precipitated in drops of rain, hail, or snow, to the earth. Nor do they stop here: the same law which precipitated them to the earth, continues to roll them on its surface, which is spherical, again into the furrow from whence they started. Thus a constant circulation is kept up. The sun is the grand cause of this circulation of waters, (as he is of the tides) and the winds, which blows them back upon the land, and how strange soever it may appear, is the remote cause of the wetness of the land, and the rivulets of the stream, to whose attractive force, and to the influence of whose heat, nearly all the phenomena in nature may be traced.

But to return. In the foregoing remarks we have endeavored to show that the operation of draining proceeds upon principle: that the nature of the water naturally pointed out the nature of the aqueducts necessary to carry it off of the land; and we might have added, the *figure* of the land, and the *fall*, their direction. We will now show the application of these principles to practice, by a reference to the figure, though little more here is necessary than a reference to the different aqueducts, which has been already made. In this figure, [illegible] the main stream which runs through the land, shows the propriety of a main carrier, A B C, and the [illegible] water of the whole low grounds, and the veins of water making across to the old channel. When this operation was performed on the land in question, spouts of water, after a rain, might be seen all up and down the sides of the ditch, like blood spouting from the section of a vein. The rain water which falls on the second low grounds, and the springs at the margin of the first low grounds, point naturally to intercepting margin ditches. The rain water which falls on the surface of the ground, between the margin ditch and main drain, call for the construction of water furrows or trenches, between the beds; the grips which intersect them, and what we have called surface ditches, as a receptacle for it. The surface ditch, *t*, which connects the margin ditch and main drain, and which nearly bisects this part of the fig., shows this, into which the grips empty obliquely. On account of the high banks that are made on the sides of these ditches, it makes it necessary to run the grips at the foot of these banks, parallel with the ditch, to avoid the necessity of deep and expensive outlets, or terminations of the trenches, through this bank. Such banks in the first instance, should never be formed, but the earth scattered at a distance over the ground. There should be as few of these surface ditches as possible. They are only necessary as outlets, for the grips and trenches, when the margin ditch and main carrier are not convenient. When they are emptied into the first of these, it should be done by the medium of a grip, which may be called a parallel grip. The beds, and of course the trenches, however, should, if the fall admit, run parallel with the main drain. Next, the rain water which falls on the hill-side suggests the propriety of a conductor at the foot of the hill, O P Q R, to turn the water from the second low grounds below, on which it would empty: and the size of the hill, or a number of hills together, and the quantity of water collected in it, show the necessity of occasional outlets, T U V W X Y, into the margin ditch. Pond water, if composed of rain water collected into sunken places, only require straight ditches cut through them, sunk below the bed of the pond, to drain them; (unless it be such as the margin pond of springs before mentioned,) such as the ponds S, S, S, &c., through which the main drain passes. When an outlet is inconvenient, or expensive to cut, and the water held by a retentive bottom, it points to the necessity of perforating the bottom. Nature teaches this when she cracks these impermeable strata by the heat of the sun, and the water sinks in the fissures. Clay lands, and the bottoms of evaporated ponds, crack sometimes to the depth of three or four feet, or more; hence the thirsty nature ascribed of these soils, and the quantity of water they drink through these throats. Where a body of low ground is generally of this character, it requires double the quantity of water in very dry weather, to produce a freshet, these fissures drinking in the water as fast as it spreads over the land. In this way, such soils become very rich, these interstices being filled with the sediment of the water: hence the streaked and veiny appearance of the soil, when cut with the spade. It is through these fissures that so much rain water is collected under the low grounds, in the permeable stratum of sand below the clay. For the water that falls near the old channel, and the springs about the same, that will answer as an outlet which answers the purpose now of another margin ditch along the opposite range of hills at the other border of the low grounds.

By a sort of *comparative* anatomy, the constant circulation of water in the earth and atmosphere, by the distribution of showers, and again draining it off by streams, may be likened to the circulation kept up in the human body by the heart, veins, and arteries: in which the ocean represents the heart, the rivers the veins, which conduct the water to it, and the clouds the arteries, by which after a certain preparation, it is again distributed over the surface, and through the body of the earth. In this system, the main drain A E C, may represent one of these large veins in the body of the low grounds (the *Vena Cava*, if you choose—the largest vein in the human body,) and the minor aqueducts, its various ramifications. The beauty of this system is, that the water is not suddenly emptied all at once into the *Vena Cava*, but by various avenues, gradually enlarging, as the water accumulates.

Thus I have endeavored to illustrate the theory and practice of draining; all the fundamental principles of which, and their application, are embraced in this figure, the most distinguishing feature of which is, the main carrier of the stream A E C.

We will now proceed to point out the manner in which it acts, in the reduction of freshets. Reclaiming of land, subject to inundation, from freshets, is a branch of draining upon a large scale. The principle is the same as in drawing off any other superfluous water. The object of the reduction of freshets, is to prevent the injury of land and the destruction of crops. The former is done by washing and disfiguring it, and the latter by drowning the plant by soaking the roots, or by destroying its structure, by caking the leaves with mud, thus stopping up their vessels. To prevent inundation, either of two things are necessary; that is, either to clean out the old channel, and occasionally straightening its bends, or changing entirely the bed of the stream. In this instance, the latter operation is exhibited. The current here is taken out of a very crooked channel, and made to run in one entirely new, and perfectly straight. The reason why this channel prevents the inundation of the land, will be the principal subject of the remarks which follow. It is entirely owing to the increased velocity, given to the current in it. This depends entirely on the form and construction of the channel. As soon as the current is introduced into this channel, it becomes subject to all the laws which govern the motion of this fluid in conduit pipes and open canals. Hence all that is known of these laws, may be here applied; and hence too, the necessity to the drainer, of a knowledge of these sciences, hydrostatics, and hydraulics, (latterly dignified with the title of hydrodynamics) which make these laws the subjects of their investigation: the first of which concerns the equilibrium, weight, and pressure of fluids—the latter, their motion. If a knowledge of dynamics, (the action of forces on solid bodies residing in motion,) is useful to every one who "owns a horse," in order to understand his speed and tractive powers, surely an insight into the above sciences, will be of no disadvantage to him who owns a canal, to understand the effects of the velocity of its current, and its power on the land. Water is subject mainly to two laws, namely: pressure, and the force of gravitation—whether it is confined and at rest, (for it never is at rest unless it is confined,) or in motion. The first is that force by which its particles press on and against each other, or on any solid body. This pressure is equal in all directions, upwards, downwards, and laterally, and is increased by the pressure or weight of the atmosphere. Upon this principle water spouts from the side of a vessel, when a hole is made into it, and as often as this operation had been performed, the property was first distinctly stated by Pascal. The second is, that force which draws bodies to the earth, or by which a lighter body is drawn by a heavier: and although here, as in the other case, millions of apples had fallen to the earth in the sight of the vulgar, Newton first discerned it, with a philosophic eye. But as these two laws are resolvable into the same (for what is the pressure of water, but its weight; and what is its weight, but the force of gravitation drawing it down?) all the phenomena of this fluid may be said to be governed by the force of gravity.

Let us see now, how the atoms of water are put and kept in motion by these two laws, which we shall consider as distinct, for the sake of clearness. First, by the force of pressure. If the sides of a vessel of water, sitting on a perfectly horizontal level plane, be suddenly taken away, the fluid within will run off in every direction on the plane, even though it have not the slightest inclination, and will continue to run and spread until there is not one particle of water above the other, to press it down when it ceases. The pressure of the water then is as its depth: and therefore as this diminishes, the pressure diminishes, until the water becomes so shallow and thin, that it ceases to run. But its velocity is as its pressure; therefore its velocity is as its depth (when unconfined, and in motion.) Therefore by increasing the depth, the fall (or inclination of the plane) remaining the same, the velocity is increased. The reason of this pressure in water is this: the atoms or particles of water, are so mobile, round, and slippery, and the cohesion of them so slight, that the upper particles pressing upon the lower ones, push them to one side: for the atoms of water are not like lead, or any other compressible substance, the particles of which may be mashed together—but the inferior atoms rather than yield to the superior by compression, slip to one side, and if not confined, they produce motion. In this thing, water or fluids differ mainly from solid bodies: the latter press only at the bottom, but the former have a lateral pressure in addition: and the nearer they approach the nature of fluids, the more they have of this property. Thus, in a barrel of shot, or sand, there is a pressure on the sides; hence such bodies have been called by philosophers, *gross* fluids. The pressure itself, which causes the motion here, is produced by the weight of the atmosphere, and the force of gravitation: but these would not produce motion in a solid body, because they have no lateral pressure. Having started the motion then by pressure, let us see how it is kept up by gravity. Water, like every other body, is subject to the force of gravitation—(with this difference, that its force on water may be overcome by removing the atmospheric pressure, and making the particles extremely light by heat.) By this law, a drop of rain falls to the earth: and if it be caught on the side of a house or inclined plane, it retards its motion some, but it still rolls on, in proportion to the elevation of the plane, until the plane be placed perfectly level or horizontal, when the law of gravitation acting perpendicularly to the plane, pins the drop of water to it and it stops.

If the plane above mentioned then be the least inclined, the motion of the water in the vessel begun by pressure, will be kept up by the force of gravitation: and the velocity or swiftness of the water will be in proportion to the inclination of the plane. Hence we infer that the velocity of the water is always in proportion to the inclination of the plane on which it runs. And therefore by increasing the inclination of the plane, we augment the velocity of the water.

The velocity of water therefore depends upon its pressure, and the force of gravitation, and these depend upon the depth and inclination of the plane. But the depth of the water depends upon the depth of the channel, and the "fall" depends upon the inclination of the plane, therefore the velocity of the water is as the depth of the channel, and the fall which it has. By increasing the depth of the channel then, and the fall, we increase the velocity of the current.

But again the discharge of the quantity of water on an inclined plane, or in a channel, (which is nothing more than an inclined plane, on which the water is confined from spreading laterally,) is as its velocity, therefore the discharge of water in any given time, is as the depth of the channel and the fall of the bottom. The velocity of water in a pipe, or open channel, is as its shortness, for the longer the tube the more the resistance the water meets with from friction on the sides, &c., hence a short tube will discharge in a given time, (of the same aperture,) more water than a long one, provided the head of water to be discharged is the same. By shortening the pipe or channel then, we increase the discharge.

The velocity of water in conduit pipes, or open canals, is in proportion to their straightness. "The motion of a fluid is further obstructed by any violent change of celerity or direction. Whether the channel be contracted or enlarged, the change is unavoidably attended by a proportional loss of impulsion. Any sharp flexure of the pipe or conduit, will occasion a still greater waste of the inciting force."* The retardation of velocity of water in canals and pipes by deflections in them, have been accurately calculated, for angles of every size. Thus, the retardation produced by a right angle, is greater than that produced by an obtuse—and by an acute angle, greater than either. We may infer therefore, that by straightening the channel, the velocity is increased.

These are some of the causes that accelerate the velocity of water, in pipes and canals. There are a variety which retard it. First, by accidental obstacles which it meets with in its course, by crookedness of the channel, &c. By its pressure against the bottom, sides of the channel, and at top by the pressure of the atmosphere against which it rubs. This pressure produces a friction, which retards the motion. This friction is greatest in a stream as you approach the sides and bottom; hence on the surface in the middle of the stream, the velocity is always greatest. Adhesion of the particles of the fluid to the sides of the channel, is another obstacle to motion. We may infer then that in proportion as these obstacles are removed, the velocity of the water is increased; and such as cannot be removed, must be overcome by increasing the velocity.

Having proved then, upon the principles of science, that the motion of fluids in conduit pipes, and open canals, is produced and continued by hydrostatic pressure, and the force of gravity—and that the velocity of this motion is increased, 1st, by the depth of the channel—2ndly, by the inclination of the bottom (or fall)—3rdly, by shortening the pipe or channel—4thly, by removing obstructions—and 5thly, straightening the channel—we will now by way of application of theory to practice, show that all these causes, are in operation to increase the velocity of the current in the canal, A E C, in the figure exhibited above.

First, it is plain that the new channel is deeper, being cut several feet deeper than the old channel, and more uniformly so. This is of great advantage in reducing a freshet; for suppose a sheet of water a foot in depth be spread over a flat 144 feet in width, and a mile in length, it may be sunk into a ditch 12 by 12 feet deep, leaving out the velocity of the water. An enlargement of the capacity of the channel, is of little advantage however, where water is constantly accumulating without increased velocity. This capacity in depth and width of the channel is not stationary, but increases with the velocity of the stream.

Secondly. It is plain that the fall or inclination of the bottom of the ditch is increased: for the fall which was before extended along a mile and a half, is brought within three-quarters of a mile. This makes the difference in the velocity and discharge of water, about the same as between the velocity and discharge of two troughs, one of which is half as long, and double of the elevation of the other (that is doubly as slanting.)

Thirdly. It is very evident by looking on the figure, the distance, and of course the channel, is shortened. The deserted part of the old channel is nearly, if not quite, double the length of the new channel; hence the pipe through which the water now flows, is shorter than the former one; and therefore the velocity and discharge is greater.

Fourthly. It is further manifest that the new

*Dr. Jamieson's Dictionary of Arts, Sciences, &c.

channel is straighter than the old one (to say nothing of other obstructions) water runs much faster in a straight channel than in a winding one, although the banks might be perfectly smooth, and gradually curving; for, when water runs in a right line, the hindermost particles push the foremost ones along straight before them; but in a curvilinear, or angular one, the hindermost particles push the foremost ones to one side out of the way, and the latter having to turn entirely round, describing a circle, and then following on, are retarded in their motion. This is the reason of those little whirlpools, at the edge of the swift part of the stream, next to the eddy parts. In the old channel there are nine large sudden curves, besides numerous smaller ones, which are avoided by straightening the channel. In the last bend, the old channel runs at right angles with itself, where it rushes against the opposite bank, which is fifteen feet perpendicular, which in freshets, would dash the water over the land this side, which of course would break over the low grounds on the other side of the old channel, between this bend and the mouth of the ditch: which is a small piece of flat squared out between this part of the old bed, and a steep hill, running within a few yards of the mouth of the canal, which was formerly subject considerably to inundation, and ought to have been appended to the figure. The curvilinear form of every channel, shows how much a current is opposed to deflections, for let these bends be as sudden as they may, they always turn by a gradual curve, instead of an angle; hence if one stream be let into another at right angles, it will soon change itself more suitable to the direction of the main stream.

Fifthly. It is plain that the stream is freed from a great many obstructions which retard the velocity, besides the bends of the channel, which like so many dams, obstruct its progress, over and through which, it breaks, to the injury of crop and land. Hammocks, (formed by trees thrown across or falling into the old channel, logs, rafts of wood, sticks and trash of every description, bushes growing on the banks, &c.) are constantly turning the stream out of a straight course, which it is ever seeking. The current now runs where there are neither stumps nor trees (on which account too, it was more easily excavated.) As to those obstructions which belong both to straight and sinuous channels, such as come under the head of pressure, friction, &c.—these are overcome in a good measure, by all those causes which increase the velocity of the current in its new channel.

Thus we have shown how the velocity is accelerated in the new channel, and the reason for it; from which it seems it must be more than doubly increased. Now as the discharge of water is as the velocity, the canal must discharge in the same time, more than double the water of the old channel. This rapid discharge prevents the accumulation of water in the channel, out of which it breaks, and inundates the land. And what water is supplied by the freshet is drawn off much faster, and of course the stream is down much quicker. This discharge of water is further increased by enlarging the capacity of the channel, which is the effect also of the velocity of the water, to which the washings, in depth and width, and the cavings of the sides, are always in proportion, for which there is abundant authority. "The increase of velocity [in a stream,] increases the action on the sides and bottom, in consequence of which the width is augmented, and sometimes also, but more rarely, the depth."—*Gregory.*

"A velocity of three inches per second, at the bottom, will just begin to work upon the fine clay fit for pottery, and however firm and compact, will tear it up."—*Du Buat.*

"A velocity of six inches will lift fine sand—eight inches will lift sand as coarse as linseed—twelve inches will sweep along fine gravel—twenty-four inches will roll along round pebbles, an inch in diameter, and it requires three feet three inches per second at the bottom, to sweep along shivery angular stones, of the size of an egg."—*Robison on Rivers.*

There is no danger of a canal of this sort washing and caving too much, a notion which with some, has obstructed this branch of draining. The laws which fix limits to channels, are as certain and immoveable, as the hills themselves. The current and the channel will always adapt themselves to each other, until they become permanent. The effect is produced in this way. As it is the increased velocity of the water which increases the depth and width of the channel, so it is the diminution of this velocity which stops the washing and caving. The velocity of the water in the canal will diminish in proportion to the enlargement of the area of the section of the canal, represented by Fig. 2; or to speak more in the style of hydraulics, "when the sections of a river vary, (the quantity of water remaining the same,) the mean velocities are inversely as the areas of the sections."—(*Gregory.*) That is, as the channel widens, (the quantity of water) the depth diminishes, and of course the hydrostatic pressure diminishes, and the water spreading over a wide bottom, the friction increases, and the velocity of the stream diminishes. Now if a freshet comes, a swift current is formed in the middle of the stream, and the water next to the sides of the ditch is more of eddy: the swift particles of water push the eddy ones to one side, and these being loaded with sand and mud; and the surface of the stream being convex, as represented in Fig. 2, which is represented by the curve line (*t a w*) they roll towards the sides, where they deposite the mud and sand. The reason of this convexity of the surface of streams, which may be seen by putting the eye on a level with the surface, is that the water in the middle, at the surface of a stream, is swifter than towards the sides and bottom, being farthest removed from friction, and being swifter, it loses some of its weight and rises, and being retarded too by the eddy water on each side which it meets with, it accumulates in the middle. The surface in the middle of some rivers, is three or four feet above the edges of the water at the sides; hence a loose boat floats to the bank. The sand and mud are deposited, while the stream is falling. Mud is always deposited by eddy water, and sand by running water. The mud suspended in the water is carried off by the swiftness of the current, while the sand is let fall. But where the water is still, the mud has time to precipitate. This is the reason why the clay is deposited on the edges, and the sand at the bottom. In long dry spells when the velocity of the stream is weakened, it gradually contracts its channel by mud and sand, and the running water fills up all the deep holes with sand, and the bottom becomes smooth. When the current gets the sand to the edge of these holes, losing its velocity, and being able no longer to carry it, it drops it in. If the drought continues, grass and bushes are apt to grow up, and form obstructions. But the next freshet that comes, will sweep out all the holes, and bear off all the banks thus formed; and so on every succeeding freshet, sweeping off the alluvial formations of the preceding one by increasing the velocity of the current, until a "king freshet," puts up a piece of masonry on the sides of the channel, and says to all succeeding ones, "thus far shalt thou go, and no farther—here shall thy proud waves be stayed." Upon this grass and bushes grow up, and thus the bed becomes permanent, from a diminution of velocity, without which, neither rock itself, nor the tenacity of the soil, could fix limits to the beds of rivers, and the earth would be washed from under us.

Having pointed out the manner in which the new channel operates in the prevention and abatement of freshets, we will briefly enumerate some of the changes which have resulted, and the benefits which have been derived to the land since the excavation of the main carrier.

In the first place, the old channel is fast filling up, and trees are growing from the bottom of it. My intention is to speed this operation, by cutting a small ditch through the middle of the bottom. This will drain the string of ponds, and by admitting the two little branches R, R, into it (which now serve to change the water in the old channel,) will form a current that with the aid of freshets will fill up all the holes.

Secondly—the land may be cultivated to the waters edge, in the old channel and the trees cut down, and the bushes grubbed up to the same, and shortly the bed itself be cultivated, for corn is now growing on a part of it, which is as high as the adjacent ground.

Thirdly—the old bed affords an inexhaustible source of manure—a compost of sand, mud and leaves.

Fourthly—all the washed places are filling up, some of which produce better than the adjacent ground. The little useless ditches also, and the ponds, S, S, S, S, are filling with mud and sand. Any pond now may be filled with sand, by passing a current into it out of the ditch; or drained, by cutting one out of it into the main drain. The land of course now is more level, and brought more in a body for the plough, which may at length cross all these places.

Fifthly—the island formed by the old and new channel is gradually becoming higher, from the deposites of the freshets. If you can ever get a current to surround a piece of land, it will soon raise it out of the reach of freshets, for the eddy water is always in the middle of a circular current, and where the eddy water is, there will be the deposites. The current in this instance takes off earth from the opposite bank all around, and throws it on the island; hence islands and peninsulas, or the bends of a channel are generally the highest parts of low land: and hence too, they are richer from the deposites, than other places. The formation of islands is handsomely illustrated by filling a vessel with water that has a little sediment in it, then whirling it round, when the sediment will be collected in a little pile in the centre of the bottom. Here the water is eddy in the middle, but formed into a swift current on the sides of the vessel, which it washes severely. In this way a single snag in the water, by forming a current around itself, in the form of a whirlpool, has formed an immense island. They are also formed by cutting across the bends of the creek.

Sixthly. The current now never breaks out of the new channel unless it is where it crosses indentations in the land, or some washed place formerly made by the current of the old channel; which when it happens, only serves to fill them up. Before it could break out of the new channel, it would run round the old, first filling up all the low places of the low grounds, (for the land through which the canal passes is the highest part of the ground generally.) This is evident from a property which belongs to water, to equalize itself, or as it is commonly called, to "seek a level." And even if it should break with violence out of the new channel, the distance to the old channel is so far, that it would soon lose its velocity, by spreading over the ground, or meeting the eddy water of the old channel, and so pour out all its sand. Lately, during the greatest freshet I have ever seen in the stream, the current at one place was diverted from the new channel, occasioned by a fish-dam below, which interrupted the fall about two feet, but instead of an injury, it was a great benefit to the land, for the sand which it gently distributed over the surface of a stiff part of the low grounds, was of incalculable benefit to it; and the wheat then growing on the spot, was not a little benefited by this top dressing of "alluvial formation."

Seventhly—any kind of crop may be now cultivated on the island, or any part of the low grounds, with perfect safety; and if there should come a freshet to inundate the land more than ordinary, and the water should spread over any part of it, it would be so much reduced, and so shallow, that it would rather be a benefit than an injury to either land or crop. In this point of view, I look now upon every freshet that may occur. It may be observed that what might be thought a very moderate freshet in the winter season, would be considered an extraordinary one in the summer, when crops are growing. It requires a vast quantity of rain even to fill the channels in the summer season.

Eighthly—the character of the land is vastly altered. Where it was inclined to a stiff clay loam, it is now of a different color and texture—not half so stiff—more open and spungy—drier, and more easily wrought.

Ninthly—the freshets are down in half the former times, and consequently less mud is deposited on the crop, which is the effect most injurious to crops in freshets. Besides, the current being swifter, less mud is deposited on that account, but more sand. A dull sluggish stream deposites nothing but mud.

Tenth—ample outlets are now offered to all the necessary ditches, ponds, &c. the margin ditch in particular, which on account of its length, (being nearly as long as the old channel) could never be kept open, is now intersected nearly in the middle, near the pond S. Before this, it emptied into this pond, which never could be drained until the main drain A E C was passed through it. Several attempts had been made to drain it by the ditch *s e*, but on account of the depth of it, (about six feet,) the little fall to the old channel, and the back-water of the old channel in freshets, which constantly filled it up, &c., they proved ineffectual till this main gut, if I may so call it, was passed through this stomach of the low grounds, where all the sand, mud, wood and water collected, and cleared it of its foul contents.

Eleventh—it should not be discarded from the list of advantages that such a ditch, answers very well the purposes of a fence. My standing pasture is in a good measure enclosed by the main drain and margin ditch: nor should a plenty of clear fresh water for the stock in it, furnished so conveniently by the new channel, be thought unworthy of consideration.

Twelfth—how advantageously such a system of draining and reclaiming could be connected with irrigation, is obvious from a single glance at the figure. An inundation of the whole plat of ground, bounded by the margin ditch and main carrier, is completely practicable, with little labor and expense.

The particular advantages here enumerated, derived to the plat of land exhibited in the figure, when properly drained and reclaimed from the injurious consequences of inundation, are not confined: they are such as would result from a general adoption of a similar method, and may be held out as some inducement of a further prosecution of a branch of husbandry, of which little hitherto has been done, and perhaps less known, than any other operation of farming. The increasing scarcity with many, of good land; the exhaustion of the highlands; an acquisition of rich and productive land by draining and reclaiming; an exemption in a good degree from the pernicious effects of droughts, so common in this country, by cultivating moist land; a connection of draining with a well regulated system of irrigation; an improvement of the country in point of health; a connection of draining with a system of enclosing; the permanency of fences on water courses, secured by straightening channels; and finally the abatement of freshets, so universally destructive to crops, and an abridgement of the time they would remain upon the land, and the preclusion of a great deal of anxiety to the farmer, are inducements that ought to render this subject more generally popular. The obstacles to such undertakings, have been already mentioned in some previous numbers of the Farmers' Register.* To these, some addition might be made of some of those that have stood in the way of success, after the work had been undertaken.

First—these are an ignorance of some of the most common properties of water, and the laws which govern its motion.

Secondly—want of judgement in executing the work, is another obstacle, by producing ill success and discouragement. This is manifested frequently, (besides in various other ways) in taking a stream out of a very crooked channel, along the foot of the hill, and running it in one equally as crooked, along the margin of the opposite hill, for the sake of a lower place, and getting the land more in a body. It is evident that nothing is gained in this instance by the diversion of the stream, it being in a situation precisely similar to the one in which it was at first, and the land still subject to excess of water, on account of its width, for the want of a main drain passing through the middle. Sometimes an attempt is made to confine a stream by a shallow ditch, in this situation, and a high dyke, in a narrow passage, between the dyke and the hill. The consequence of this is, the water when a freshet occurs, on account of the narrowness of the passage, the hydrostatic pressure of the water (which is as we have already seen, as powerful laterally, as in any other direction,) and the crookedness of the channel, the water bursts through the dyke, over the land, and makes a joke of the vain and injudicious attempts of the drainer to confine it. Besides, the water here running nearly on the surface of the ground, (the hill and the dyke answering in the place of banks) it makes all the land adjoining the dyke, too wet for cultivation; and the channel after awhile, on account of the deficiency of "fall," will fill up with mud, and render the stream still more liable to overflow. Water is a dangerous element to trifle with, where you run counter to all its laws and properties—(as in this case,) but concur with these, and it is easily managed. When the flood-gates are hoisted, and the freshets are high, if you then attempt to confine it in a shallow, level, crooked, and confined channel, "it will laugh at your calamity, and mock when your fear cometh," and the desolation of your crop, like a whirlwind. The ditch should be cut through the middle (if practicable,) of the land, for the sake of the fall, straightness of the channel, its depth, and higher banks, and to act as a main drain.

Thirdly—meeting with rock, is another obstruction; on the account of which, numberless undertakings have been abandoned, after much labor and expense. To avoid these, (which are apt to be met with, in hills and rising ground in the flat land) the stream should not be conducted too much out of its general straight course, which is the case when it is taken through ground much higher than the bed of the old channel, or is cut into the hill-side, when it meets with knolls, or little plats of rising ground. As they are generally of short extent, the new channel should not be curved to avoid them. In the ditch under consideration, mentioned above, there were several places of this description; but as they were small, and the rocks were detached, they offered no obstruction, except in one place, where the canal approached very near the foot of the hill, at the pond S, where the rocks which projected out of the hill, (which formed one bank of the ditch there) and run partly across the bed, were a little stratified; but they were easily removed, and the current has a sufficient passage.

Fourthly—the fear of losing too much land by the washing and caving of the ditch, is with many, an obstacle to ditching on a large scale. But it must be recollected that where we lose land in one place, it is counterbalanced by gaining it in another; for every foot washed away by the new channel, one is added on to the old, by the depositions of freshets, besides enabling you to till nearer the water, and the general acquisition of

---

*See communications *On Draining*, Nos. 7 and 12, Vol. I.

land by drainage, and the prevention of freshets.

Fifthly—even religious scruples, or rather superstitious notions, have troubled many upon this subject. They seem to think it sacrilegious to divert a stream from its ancient bed, where the Almighty has placed it, and put it into one entirely new. But let a flood occur that threatens total destruction to their crops, and they are perhaps the very first persons that lose their submission to an overruling providence. This spice of devotion to streams, is very ancient. I imagine, should any one attempt to change the bed of the sacred Ganges (as it is called,) all the pilgrims of the East, would be in arms against him; where they resort in "numbers numberless," to pay their superstitious homage to that watery god, and to sacrifice their offspring. Some may be surprised to hear that such an obstacle should exist to draining; but such is the fact: nor need we be surprised at it. Superstition has in all ages retarded, not a little, the progress of knowledge. The suggestion of Gregory, that the sun was fixed, and the earth revolved, was condemned as a heresy by the church, and the support of it provided a prison by the Inquisition, for Galileo. But we will not digress.

Sixthly, and lastly—the fear of incurring expense, has been the prime cause which has obstructed this kind of work. The work is begun, and a pretty good way is made into it, when all at once, it is abandoned. "Too expensive—it will cost more than the land is worth to finish it:" and thus all the labor is entirely lost. A little rock, perhaps, is found in the bottom of the ditch, and for fear of spending 40 or $50 to remove it, $400 in previous labor is entirely thrown away, and a great deal of land destroyed. How many undertakings of this sort, which either from want of judgement in the design, or from partial execution of the work, or from both causes, are every where to be met with, and remain the monuments either of the ignorance, or the penuriousness of the undertakers.

To do the work effectually, and profitably then, we must be determined to go through with it, cost what it may. If we first "count the cost," and find it likely to be profitable, if it cost half the worth of the land, or even the whole worth of the land, (that is what it would sell for before draining and reclaiming,) for it might increase the value of some land that was not worth five to twenty dollars, or even to fifty. Nothing is more expensive than the cultivation of wet, undrained land, (and whose crop is not pitched in a good portion of this sort every year?) and nothing more deceptious. The land has the appearance of being rich, and indeed it is, and we try it every year, though we are as often disappointed.

It is better to cultivate the most barren hills on your plantation, than the richest spots subject to excessive wetness; for they not only fail of a small produce, but they produce nothing at all, whereas the most barren hill will produce something. In fact, the "sobbed" parts of a plantation are the poorest parts on it, when permitted to lie undrained—but if thoroughly drained, the very richest. From the value of not more than a cent, they may be suddenly advanced to 20 or $30 per acre, or more. And the value of the crops lost from excessive wetness, for one or two years, would do the work effectually. Is it not profitable then, to lay such places dry if ditching is expensive? Where profits counterbalance expense, however great, there is no expense at all.

The straightening of a part of the channel of the stream, on which I reside, (Twidie's Creek,) by cutting the ditch exhibited in the figure, and an attentive operation of its observation for five or six years, has given rise to the foregoing remarks. If they can be of any benefit to any one having lands in a similar situation, the author of them will feel amply requited for his contribution.

From the Ohio Farmer.

THE FRUIT-DRIER.

Having found a fruit-drier a convenience in family economy, I am induced to give a short description of it, and its uses, *pro bono publico*. Take two boards 18 inches wide and 4 feet long, set them on end by the side of the house—on the top nail a cover, extending a little over the front, and leaving an inch open at the back, to allow the air to pass freely—make 10 or twelve drawers 3 feet long, 3 inches deep. The sides of common stuff, the bottoms of half inch stuff, split into narrow slits, and with brads fastened five-eighths of an inch from each other, so as to let the air pass freely; on these slats lay the fruit; the drawers may be taken out on sunny days, and in case of rain, and at night, they may be replaced. In this way the fruit is never moulded, and much labor is saved. The fruit requires no moving, and the drawers can be replaced with very little labor, and the drying goes on in rainy weather and at night.

From Loudon's Gardener's Magazine.

LIQUID MANURE.

Liquid manure may be here [at Ghent] named, and very justly so, their *summum bonum;* as if applied when the corn is sprouty, or just before a rain, it has an effect which no other manure can have. It destroys insects, and throws a surprising degree of vigor into the crops. It is pumped [from the tanks under ground, into which it is conducted by drains from the stables, &c.] into a barrel-shaped water cart; and, when brought upon the land, the plug is taken out, and the liquid, flowing over a board something in the shape of a fan, as the cart proceeds, is dispersed on both sides, over a space, perhaps, of 4 or 5 feet. The cart has generally three wheels.

From the Cultivator.

FENCE POSTS.

An excellent method of rendering these durable in the ground, is published in the American Eagle. It consists, 1. In peeling the posts, and in sawing and splitting them if too large; 2. In sticking them up, under cover, at least one entire summer; and 3. In coating with hot tar, about three feet of the butt ends, which are to be inserted in the ground—after which they are ready for use. We have no doubt the advantages of this mode of preparation will more than remunerate for labor and expense. Our reasons for this belief are briefly as follows: The sap of all non-resinous trees, will ferment in the presence of heat and moisture, and cause the decay of the wood. To prevent this natural consequence, the first object should be, when a tree is felled, to expel the sap from the pores of the wood. This is done by peeling, splitting, sawing or hewing, and exposing the wood to the drying influence of the sun, or at least of the air. The process is facilitated too by immersing the wood in water for a time, which liquefies the sap, and favours its expulsion. And when the moisture has been expelled, the next object is to keep it out, by paint, tar or charring. In the mode recommended above, the moisture is expelled by the peeling, sawing and summer-drying, and its return is prevented by the coating of tar. The retention of the bark upon timber is particularly prejudicial, not only in preventing evaporation, but affording shelter to various species of the borer, which, under its cover, carry on their depredations upon the timber. We have seen pine logs nearly destroyed in a summer by worms, where the bark had been left on, while those which had been peeled remained uninjured. The best timber is obtained from trees which have stood a summer, or a year, after they have been girdled and peeled.

From the New York Farmer.

SAXONY SHEEP.

[The following is an extract from a reply to a paper republished in the Farmers' Register p. 45 Vol. III.

There is in Saxony a breed of sheep which were introduced and reared with great care by Augustus, Elector of Saxony and King of Poland, which, in commemoration of the introducer, have been called the electorial breed. I was brought up in that country to rural husbandry, particularly to the care and management of sheep, and perfectly acquainted with the purest and most celebrated flocks. From these I selected my sheep, and brought them to this country. They bore the fatigues of the voyage remarkably well, and arrived in safety. I sustained some little losses at first, from being a stranger to the peculiarities of the country, from having to hire my sheep kept, for want of suitable accommodations, and of such fodder as I wished. During the last eight years, and since I had a farm of my own, I have not lost over $1\frac{1}{2}$ per cent.: for the last year not more than 1 per cent. The last two winters I had no loss, and the last year I raised 101 lambs, from 100 ewes, one only of my eyes having twins. The sheep which R. speaks of do not shear more than $2\frac{1}{4}$lbs. My flock, last year, of 200 ewes and lambs, averaged 2 lbs. $6\frac{1}{2}$ oz. If I had had a proportion of wethers, they would probably have averaged 3 lbs. My grown bucks sheared $4\frac{1}{2}$ lbs. He says they (that is, the sheep he speaks of,) are poor nurses: my ewes are uncommonly good. All these facts can be abundantly proved from my sheep records, in which births and deaths, and every thing of importance, is recorded, and from credible witnesses. All these facts, in which there is no guessing, show conclusively that R.'s statements about the pure breeds of Saxon sheep did not allude to my sheep at all; and therefore I hope there will be no unkind feelings between us.

Respecting the "*miserable*" quality of the meat, if R. will produce the best sample of the South Down mutton he can find, I will meet him at any place he shall name with a sample from my Saxons: both shall be cooked in the same manner; he shall select one or more of the most accomplished connoisseurs in good eating, and I will rest that point on their decision.

I have but one little statement more to add, and I will then leave the subject to the public. The prices current of wool in New York, given in the Cultivator for the last month (May) are for Saxony, 80 cents; for half-blood 53 cents, and for native, 33 cents. Now, allow my ewes to produce $2\frac{3}{4}$ lbs., (and they will rather over-go than fall short of it.) then at 80 cents the fleece will bring \$2 40. Allow the South down ewes to shear 4 lbs. and allow it be to equal to the half-blood merino, and the amount will be \$2 12. Allow the Bakewell breed to produce 7 lbs., which is 1 lb. more than R. rates them: this at 33 cents will be \$2 31. The three fleeces will stand thus:

Saxon,	2 40
South Downs,	2 12
Bakewell,	2 31

With these remarks, I submit the subject.

HENRY D. GROVE.

From the Farmer and Gardener.

DIRECTIONS FOR SOWING THE SEED AND RAISING THE PLANTS OF THE WHITE ITALIAN MULBERRY TREE.

1. To sow an ounce of seed, prepare a bed 50 feet long and 4 feet broad. Manure it well with a compost composed of $\frac{1}{3}$ stable manure, $\frac{1}{3}$ ashes, and $\frac{1}{3}$ decomposed leaves from the woods, or garden mould: dig deep, pulverize finely, and then lay the bed off in drills 12 inches apart, $\frac{1}{4}$ or $\frac{1}{2}$ of an inch deep; sow the seed as thick as you would onion or parsnips; cover with rich mould, press the mould down gently, but sufficiently to cause the seed to come into contact with the earth; and should the weather be dry, water the seed bed every other evening, it will assist in promoting the germination of the seed and vigorous growth of the plant.

2. Keep the beds clean of weeds; and should they receive an occasional watering with suds or soot and water, say once a week after they are up, if planted this month, August, they will be fit to transplant into nursery rows in April next, or if not desirable to be so removed, they may be permitted to remain until the ensuing spring, care being taken to keep the bed clean of weeds, the earth stirred, and watered in dry seasons.

3. The second year, if not removed before, the plants must be removed into the nursery rows, which must be prepared as for any other crop. The ragged roots being taken off and the tap root shortened, the plants must be planted out 12 inches apart in rows three feet apart, the earth to be well trodden around the plant. As before, the earth must be kept open and free from weeds.

4. At two years old, the plants may be planted out into hedges, at 18 inches apart in rows six feet wide. The ground should be prepared as before directed and some good rich mould put into the holes, to be pressed around the plant. If intended to be planted out as standard trees, 20 feet square

apart would be good distance; but in that case the plants should not be transplanted until they are about an inch in diameter. In either case they will require trimming and topping, and if kept as hedges should be treated as other hedges are.

ROBERT SINCLAIR, JR.

From the Salem Landmark.

PROFESSOR SILLIMAN'S SECOND LECTURE ON GEOLOGY, ABRIDGED.

Internal fire or Volcanoes.

The lecturer said it was a tremendous thought, that the centre of the earth was a vast mass of liquid boiling flame. But that it was so, was in the highest degree probable. He then glanced at the volcanic regions on the globe, beginning with Iceland, which is wholly volcanic, being the hottest and the coldest country in the world. He said it was well ascertained that Sweden was rising out of the water, at the rate of about four feet in a century; that is, the ocean is gradually receding from the shores of that country, as the water marks plainly indicate. This he supposed to be the expansion of that part of the crust of the earth, produced by the internal heat.

In England there are no volcanoes, and no evidence that there ever was any. But in the city of Bath there are heated waters which are known to have existed in their present state for more than two thousand years. These waters can be heated only by internal fires.

In France there is a series of extinct volcanoes along the borders of the Rhine. They are also to be found in Spain and in Portugal, in Italy and in the islands of the Mediterranean. A volcanic island emerged from this sea about four years ago. There is, therefore, reason to believe it reposes on a bed of fire. There is abundant evidence that volcanoes have been in Palestine: the last probably were those connected with the destruction of Sodom and Gomorrah. They are clearly traced around the Caspian Sea, and in the centre of Asia.

In the Azores, the existence of forty volcanoes is discoverable. So likewise they are found in the Madeira, the Canary, and the De Verde Islands, in Madagascar, Bourbon, along the Red Sea, in Sumatra, Java, Kamschatka, and on the north west coast of America. Mexico is a peculiar volcanic region, and so is the whole western side of South America. They have not existed on the eastern side. Sufficient relief has thus far been had on the western coast, but should these safety valves be obstructed for any length of time, very probably there would be volcanoes on the eastern coast.

The Pacific Ocean to a very great extent stands upon a basis of fire. There are on the globe three hundred chimneys, through which the fire can escape from its prison in the centre of the earth. Volcanoes are very justly denominated safety-valves, the conservative principles of our globe.

The invariable precursor of a volcano is an earthquake, generally attended with loud detonations. Chasms are opened in the earth, and sometimes cities are swallowed up. Changes in the atmosphere are also visible. The seasons are irregular; animals utter cries of alarm; dizziness of the head is experienced by men.

The waters of the Ohio were affected by the earthquake at Lisbon. In the eruption of a volcano, rocks are dashed against each other, and either ground into powder, or broken into fragments. White smoke first emerges from the crater, then black, rising like the trunk of a tree.

The most remarkable volcano on the globe is in the island of Hawaii, one of the Sandwich group. This has been visited and scientifically examined and described by the American Missionaries, to whom Mr. Silliman awarded high praise, not only for their christian zeal but for attainments in science and literature. Science as well as christianity is under obligation to them for their devotedness and enterprize.

The cause of volcanoes is internal fire. That it exists, there is very satisfactory evidence.—There is a gradual increase of heat as we descend into the interior of the earth. At two miles below the surface, water will boil; at ten miles below, rocks become red hot. The frozen [or solid] crust of the globe is supposed to be about forty miles thick. We cannot be perfectly secure against the effects of this fire. The crust of the earth is at any time liable to be broken. Our security and dependence are upon Him who made the world, who gave to matter all its laws, and who controls its wonderful movements.

The sun is a body of fire, occasionally exhibiting dark spots on its surface. Mr. Silliman suggested those spots might be produced by the formation of a freezing crust like this which covers our globe. If so, the time may come when the sun shall all be frozen over, and there shall be no more light or heat to cheer or warm this solar system. For the consolation of this audience, he said they would not be here when such an event should happen.

For the Farmers' Register.

ACCOUNT OF MARLING LABORS, EXECUTED UNDER GREAT DISADVANTAGES.
